Abstract

The selective serotonin reuptake inhibitor (SSRI) fluoxetine, which is registered for a variety of psychiatric disorders, has been found to stimulate the cAMP responsive element binding protein (CREB), increase the production of brain-derived neurotrophic factor and the neurotrophic peptide S100β, enhance glycogenolysis in astrocytes, block voltage-gated calcium and sodium channels, and decrease the conductance of mitochondrial voltage-dependent anion channels. These mechanisms of actions suggest that fluoxetine may also have potential for the treatment of a number of neurological disorders. We performed a Pubmed search to review what is known about possible therapeutic effects of fluoxetine in animal models and patients with neurological disorders. Beneficial effects of fluoxetine have been noted in animal models of stroke, multiple sclerosis and epilepsy. Fluoxetine was reported to improve neurological manifestations in patients with Alzheimer’s disease, stroke, Huntington’s disease, multiple sclerosis, traumatic brain injury and epilepsy. Clinical studies so far were small and often poorly designed. Results were inconclusive and contradictory. However, the available preclinical data justify further clinical trials to determine the therapeutic potential of fluoxetine in neurological disorders.
Introduction

The selective serotonin reuptake inhibitor (SSRI) fluoxetine is widely used to treat depression, obsessive-compulsive disorder, bulimia and panic disorder. It became FDA approved in 1987. Fluoxetine increases extracellular serotonin (5-HT), which activates 5-HT receptors. The 5-HT receptors are classified into 7 classes (5-HT 1 to 7) with many subclasses. The effect of activation of 5-HT receptors is diverse and dependent on the class of receptor. The 5-HT system is complex and subject to continuing research. Fluoxetine was also found to stimulate 5-HT2 receptors directly.

Although the precise mechanism for its beneficial effects in psychiatric disorders is uncertain, fluoxetine has been shown to modulate important cellular functions that are thought to be important for neuronal cell survival and neuroplasticity, including the regulation of the transcription factor cAMP response element binding protein (CREB), the production of neurotrophic factors, the regulation of neuronal energy supply, and the opening and closing of ion channels.

The aim of this article is to give an overview of the neurobiological effects of fluoxetine that could be useful for the treatment of neurological disorders, and to review the reported effects of fluoxetine on neurological disorders and their animal models. We performed a PubMed search with the words fluoxetine, and neurologic(al), neuroprotection, Alzheimer’s disease, dementia, Parkinson’s disease, multiple sclerosis, stroke, Huntington’s disease, epilepsy and brain injury. Articles only reporting effects on psychiatric symptoms were excluded. All available English written reports of animal and patient studies published online before May 2007 were included.

Neurobiological effects

An overview of the articles reporting on the neurobiological effects of fluoxetine that could be useful for the treatment of neurological disorders is shown in table 1 (page 20).

Effects on CREB and neurotrophic factors

Chronic treatment with fluoxetine upregulates cerebral CREB expression and phosphorylation in rats and mice. CREB is a transcription factor, which induces the expression of genes with roles in cell survival, energy metabolism and regeneration. This transcription factor is so important that the search for drugs that increase CREB levels has been called the search for the ‘Holy Grail of neurological therapeutics’.

One of the CREB regulated genes is coding for brain-derived neurotrophic factor (BDNF). BDNF is important for the normal development of the human brain and has a critical role in neural plasticity. Decreased levels of BDNF may play a pivotal role in the
neurodegeneration associated with aging, Huntington’s disease, and Alzheimer’s disease. Increased BDNF expression was found in multiple sclerosis lesions and proposed as a mechanism for neuroprotection. Fluoxetine elevates the concentrations of BDNF in rat brain, and enhances the production of S100β in astrocytes. S100β, which is mainly produced in astrocytes, has paracrine and autocrine effects on neurons and glia. It enhances neurogenesis, but leads to apoptosis in high concentration. S100β elevation is associated with treatment response in multiple sclerosis patients on interferon-β, and S100β administration in an in vitro model of traumatic brain injury reduced delayed neuronal injury.

Effect of fluoxetine on neuronal energy supply
The energy supply of neurons is complex and incompletely understood. According to the astrocyte-neuron lactate shuttle hypothesis, lactate produced from astrocyte glycogenolysis is shuttled to neurons and axons and serves as metabolic fuel, especially during neuronal activation. Fluoxetine is able to enhance glycogenolysis in cultured astrocytes and could thus theoretically improve energy supply of axons and neurons.

Effect of fluoxetine on electrolyte channels
Fluoxetine inhibits voltage-gated calcium channels in rat cerebral cells and sodium channels in bovine adrenal cells. This may prevent neurotoxic intracellular calcium overload in neurons, which is a key mechanism in neuronal death in both acute conditions, such as ischemia and hypoxia, and neurodegenerative processes. In ischemic rat spinal cord, white matter inhibition of the Na⁺/Ca²⁺-exchanger was found to be neuroprotective.

Fluoxetine decreased the conductance of the mitochondrial voltage-dependent anion channel (VDAC) in mitochondria isolated from rat liver. VDAC has an important role in the release of cytochrome c, an important step in apoptosis. Inhibition of the VDAC by fluoxetine protected against staurosporine-induced apoptotic cell death in human U-937 cells.

Studies in neurological disorders and their animal models
An overview of the articles reporting effects of fluoxetine in animal models of neurological disorders and in patients with neurological disorders is given in tables 2 (page 22) and 3 (page 25).
Parkinson's disease

In patients with Parkinson's disease neuronal destruction of the substantia nigra reduces the amount of dopamine in the striatum, which impairs motor function. Neuronal cell death may be caused by mitochondrial dysfunction resulting in decreased energy production and increased intracellular Ca$^{2+}$ levels. Fluoxetine might be neuroprotective by preventing elevations of intracellular Ca$^{2+}$ levels, promoting neuronal energy supply and the release of neurotrophic factors by astrocytes.

In a rat model of Parkinson's disease, fluoxetine reduced the availability of extracellular dopamine after L-DOPA administration, and it was suggested that SSRIs might worsen motor function in patients with Parkinson's disease. In agreement with this observation, a number of case reports and small studies suggested that fluoxetine may worsen motor symptoms in Parkinson's disease. However, an open pilot study in 14 patients who used fluoxetine 20 mg daily for 1 month found no change in rigidity and bradykinesia scores, but a decrease in tremor severity was observed. Another open label study of 62 depressed patients with Parkinson's disease showed that SSRIs were well tolerated and did not change motor symptoms as measured with the Unified Parkinson's Disease Rating Scale (UPDRS) after 6 months of treatment.

In three reports the effects of repetitive transcranial magnetic stimulation (rTMS) and fluoxetine in depressed patients with Parkinson's disease were compared. Both fluoxetine and rTMS improved the Stroop (coloured words and interference card) and Hooper and Wisconsin (perseverative errors) test performances. Increases in regional cerebral blood flow (rCBF) in the posterior cingulate gyrus and decreases in the right medial frontal gyrus were noted with both fluoxetine and rTMS. Compared with rTMS, fluoxetine intake was associated with a relative rCBF increase in the occipital lobe. The Mini Mental State Examination (MMSE), which is an 11-item examination of cognitive functions with higher scores indicating better cognition, improved when both groups were analyzed together after 8 weeks. The motor score did not change significantly although there was a trend towards worsening in the fluoxetine group.

Alzheimer’s disease

In Alzheimer’s disease amyloid-$\beta$ and tau make up the plaques and tangles that are believed to cause the progressive neurodegeneration, which leads to dementia. Impaired energy metabolism is found in Alzheimer’s disease, and an increase in CREB phosphorylation has been suggested to offer promise as therapeutic intervention for counteracting neuronal damage in Alzheimer’s disease.

In a small randomized, double-blind trial, 18 patients with Alzheimer's disease and major depression were treated with fluoxetine 10 mg/day and 19 with amitriptyline 25 mg/day during 6 weeks. Scores on the MMSE increased significantly with treatment when both
groups were analyzed together. In the fluoxetine group the MMSE increased from 20.0 at baseline to 21.4 at day 45. Dropout rates were very high; 55% for amitriptyline and 22% for fluoxetine. A randomized, double-blind trial compared the use of fluoxetine 20 mg/day, haloperidol 3 mg/day and placebo in 15 non-depressed patients with disruptive agitated behaviors (5 per group) over a period of 6 weeks. Besides more side-effects in the active treatment groups no significant differences were found.

No improvement of MMSE was noticed in a randomized, double-blind, placebo-controlled trial of 15 depressed patients on fluoxetine up to 40 mg/day during 6 weeks.

In a 8-week, double-blind, placebo-controlled study of 58 non-depressed patients with mild cognitive impairment, which may be a prodromal state of Alzheimer's disease, fluoxetine improved memory and cognition, measured with the MMSE and subtests from the Persian standardized Wechsler Memory Scale III (WMS-III).

Stroke

In ischemic stroke neurons die when blood supply falls below the infarction threshold of 8-10 mL/100 mg/ min. Neurons in the so-called penumbra, where the blood flow is between the infarction threshold and the functional threshold of 18-22 mL / 100g/ min, can die due to lethal biochemical processes or be rescued by vessel recanalisation or neuroprotective interventions. Recovery after stroke is not only dependent on the survival of the neurons in the penumbra, but also on brain plasticity. Fluoxetine could be neuroprotective in the acute phase (ion channel blocking, enhanced energy metabolism and neurotrophic factor release) and improve brain plasticity during stroke rehabilitation (neurotrophic factors).

After induction of focal ischemia in rats, fluoxetine did not alter the degree of recovery of function compared to non-treated rats after 4 weeks of treatment. In another study, fluoxetine administered 7 days before and up to 28 days after induction of focal cerebral ischemia did not influence sensorimotor recovery in rats. However, low dose fluoxetine given during 7 days post-partum reduced functional deficits in rats with neonatal hypoxic ischemic brain injury.

In 8 non-depressed stroke patients, a single dose of fluoxetine appeared to improve motor skills of the affected side. During rehabilitation 1 to 6 months after stroke, severely disabled patients showed significantly more often good recovery after 3 months of fluoxetine treatment, compared to placebo and the norepinephrine reuptake inhibitor maprotiline. Two other randomized, double-blind, placebo-controlled trials including 104 and 31 stroke patients were mainly focused on the antidepressant effects of fluoxetine and found no benefit on functional recovery after respectively 45 days and 12 weeks of treatment.
Spalletta et al. looked at the effect of sertraline (n=21) and fluoxetine 20 mg (n=29) on patients with and without alexithymia, a condition in which patients have problems identifying and coping with feelings. A significant increase of MMSE after 8 weeks of treatment in the 32 patients without alexithymia was noticed.\(^{54}\)

**Huntington’s disease**

In patients with Huntington’s disease the slowly progressive neuronal loss in the basal ganglia causes a movement disorder (characteristic chorea) together with a cognitive and affective disorder. An altered energy metabolism is hypothesized to be important in the pathophysiology of Huntington’s disease.\(^{55}\) Fluoxetine might have a neuroprotective effect by increasing energy metabolism and the production of BDNF.

Two patients with Huntington's disease responded well to fluoxetine treatment. Both showed motor improvement and one patient's cognitive functions also improved. Beneficial effects did take 4-6 months to develop and lasted several years.\(^{56}\) A randomized, double-blind, placebo-controlled trial in non-depressed Huntington's disease patients failed to show substantial clinical benefits of fluoxetine treatment after 4 months, although a slight reduction in agitation and in the need for routine care was found.\(^{57}\)

**Multiple sclerosis**

In the beginning of their disease about 80% of the patients with multiple sclerosis have symptoms that come and go (relapses) resulting from focal inflammatory demyelination in the central nervous system (CNS). After 10 to 20 years most patients experience gradual increasing disability, which is caused by a more diffuse progressive axonal loss. Mitochondrial failure, which gives dysfunction of electrolyte channels and leads eventually to toxic intracellular calcium overload, is suspected to play a pivotal role in the axonal dysfunction and degeneration in multiple sclerosis.\(^{58}\) By improving energy metabolism and by blocking sodium channels, fluoxetine might protect axons in patients with multiple sclerosis.

In mice with chronic relapsing experimental allergic encephalomyelitis (EAE), an animal model for the inflammatory lesions of multiple sclerosis, fluoxetine prevented worsening of neurological signs, prolonged survival, and reduced CNS inflammation and axonal damage compared to untreated animals.\(^{59}\)

In a letter to the editor a psychiatrist reported a patient with multiple sclerosis who suffered a worsening of symptoms after initiating treatment with fluoxetine.\(^{60}\) A number of psychiatrists replied that multiple sclerosis patients on treatment with fluoxetine on the contrary remained quite stable.\(^{61}\)
In a preliminary open study of 11 patients with multiple sclerosis, 2 weeks of fluoxetine administration increased cerebral white matter N-acetylaspartate levels on magnetic resonance spectroscopy, suggesting an improvement in axonal mitochondrial energy production.\textsuperscript{62} Trends towards an improvement of walking ability and fatigue were also noted.

\textit{Traumatic brain injury}

Trauma to the head causes permanent and reversible damage to neurons. Improved energy metabolism and increased production of neurotrophic factors by the administration of fluoxetine might prevent irreversible loss of neurons and promote plasticity in patients with traumatic brain injury.

In a rat model of moderate to severe traumatic brain injury, fluoxetine treatment during 15 days did not improve motor performance.\textsuperscript{63}

In an open-label investigation of 5 head-injured patients, fluoxetine not only improved mood, but had also a beneficial effect on several measures of cognition after 8 months of treatment.\textsuperscript{64}

\textit{Epilepsy}

Epilepsy is caused by a reduced membrane stability of neurons. Both genetic predisposition and neuronal damage increase the susceptibility for epileptic seizures. Treatment is aimed at increasing the membrane stability. By blocking sodium and calcium channels fluoxetine might improve membrane stability. Fluoxetine reduced seizure activity in many animal models of epilepsy.\textsuperscript{65,66,67,68,69,70} However, one study reported an increase in epileptic activity after treatment with fluoxetine in a rat epilepsy model.\textsuperscript{71}

In an open-label, add-on trial of fluoxetine in patients with complex partial seizures with and without secondary generalization, 6 patients showed complete disappearance of their seizures and the remaining 11 patients had a 30% reduction in seizure frequency.\textsuperscript{72}

It is stated that despite some case reports of worsening of seizure activity, antidepressant drugs can have anticonvulsant effects when used in usual dosages.\textsuperscript{73,74}

\textbf{Discussion}

Caution should be taken to extrapolate the results of in vitro studies to in vivo effects. In cell cultures the concentration of fluoxetine used (1-50 \(\mu\)M) mostly exceed therapeutic plasma levels in patients (1-3 \(\mu\)M) and the effect of fluoxetine might be overestimated.
However, drug concentrations of fluoxetine in the human brain are reported to be 20 fold higher than plasma levels and concentrations of up to 50 μM might thus be reached in the human brain. Beneficial effects of fluoxetine were noted in animal models of stroke, multiple sclerosis and epilepsy. In these studies higher dosages of the medication (1.0 -20 mg/kg/day) were used than in clinical use (20-80 mg/day; = 0.25 – 1.0 mg/kg/day) and the results must therefore also be regarded cautiously. In patients with Parkinson’s disease, fluoxetine was well tolerated but no positive effects on symptoms of the disease process were reported. In Alzheimer’s disease one positive study was found in mild cognitive impairment. The other studies had only 6 weeks of follow-up and could not find beneficial effects. In stroke patients initial claims of a beneficial effect of fluoxetine on motor recovery could not be confirmed in a larger study with longer follow-up. In Huntington’s disease a relatively large, well-designed trial with 4 months of follow-up could not find better performance of patients treated with fluoxetine compared to placebo-treated patients. In epilepsy, multiple sclerosis and traumatic brain injury good studies are lacking.

Many clinical studies were performed in depressive patients, and it is uncertain whether improvement of neurological symptoms was influenced by improvement of the underlying depression. Also it is difficult to measure effects in neurodegenerative disorders since progression is slow, clinical scales are insensitive and good surrogate markers are lacking. Underestimation of therapeutic effect is possible since at least several weeks of treatment are necessary before plasma levels of fluoxetine become stable.

Small studies with a number of other SSRIs have also shown an indication for a possible beneficial effect in some neurological disorders: paroxetine and citalopram in patients with Parkinson’s disease, sertraline in patients with traumatic brain injury, and fluvoxamine in patients with epilepsy. Since distinct SSRIs have different affinities for the serotonin receptors it is not possible to generalize the results of fluoxetine to all other SSRIs.

Although clinical studies so far are inconclusive, the preclinical findings justify further trials with fluoxetine and perhaps other SSRIs in patients with neurological disorders.
