Abstract

Background. Risk factors for mortality in community-residing persons developing congestive heart failure (CHF) and acute myocardial infarction (AMI) may differ for males and females.

Method. Persons from the Groningen Longitudinal Aging Study with incident CHF (N=274) or AMI (N=198) were identified between 1993 and 1998 and their survival status was collected in 2001. Risk factors are assessed prior to the cardiac diagnosis.

Results. The 1-, 5-, 7-year survival rates were 65, 53, 50% for AMI and 74, 45, 32% for CHF. Multivariate analyses showed that male gender, high age, smoking, diabetes and low physical function were risk factors for mortality among persons with CHF. For AMI, 1 month mortality was related to high age and baseline low body mass index, while longer term mortality was related to male gender and high age. In addition, diabetes increased longer term mortality among females but not among males with AMI. Depression was not a risk factor for mortality for either condition in either gender.

Conclusion. Males with CHF or AMI have worse survival rates compared to females. Risk factors for mortality are predominantly similar for males and females, except for diabetes which is a risk factor among females, but not males with AMI.

Introduction

Coronary heart diseases (CHD), including acute myocardial infarction (AMI) and chronic heart failure (CHF), are associated with increased mortality (Goldberg et al., 1999; Levy et al., 2002). There are differences in the incidence and clinical presentations of CHD between males and females (Barrett-Connor, 1997; Chen et al., 1999; Van Jaarsveld et al., 2002). Better survival for female compared to male patients is reported (Kober et al., 1996; Levy et al., 2002). In AMI patients, contrasting results are found depending on whether short-term (within 1 month) or longer term survival is studied. Increased mortality rates within 1 month after diagnosis is reported in young but not in older females (>65 years) (Abildstrom et al., 2003; Chen et al., 1999; Rosengren et al., 2001). Others report no gender difference (Galatius-Jensen et al., 1996) or increased short-term mortality among males (MacIntyre et al., 2001). Although results are contradictory, most studies among older persons indicate worse survival among males on the long term (Kober et al., 1996; Vaccarino et al., 2001).

The question remains what causes gender difference in mortality among CHD patients. One explanation concerns gender-related differences in the prevalence of risk factors for overall mortality such as smoking, body mass index and comorbidity (Yusuf et al., 2004). Second, risk factors may have differential effects for males and females. A meta-analysis...
showed that the impact of diabetes on CHD mortality is greater for females (Lee et al., 2000), while males show greater effects of disability, cholesterol and smoking (Janghorbani et al., 1993; Kattainen et al., 2004; Marang-van de Mheen et al., 2001).

Classic risk factors for mortality associated with CHD include gender, age, socio-economic status (Fried et al., 1998), marital status (Coyne et al., 2001), health status (e.g., hypertension and diabetes mellitus (Kannel and McGee, 1979; Sachdev et al., 2004), and potentially modifiable factors related to behavior (e.g., smoking and body mass index) (Fried et al., 1998). In addition, low self-rated health has been found to be a predictor for mortality (Idler and Benyamini, 1997). Although the mechanisms by which a self-rating of health predicts future mortality are diverse and largely unknown, ratings of self-rated health undoubtedly reflect inadequately measured and unmeasured objective factors, and it is suggested that the meaning of these self-ratings differ for males and females (Spiers et al., 2003). Depression has attracted particular attention because it is highly prevalent, a robust predictor for mortality in many populations, especially among AMI patients, and potentially modifiable by treatment (Barefoot et al., 1996; Frasure-Smith and Lesperance, 2003; Van Melle et al., 2004).

This study aims at identifying independent risk factors for mortality among community-residing persons who develop either CHF or AMI and determines whether effects of risk factors differ according to gender. Data originate from the Groningen Longitudinal Aging Study (GLAS) which offers an unusual opportunity, since it includes up to 8-year follow-up of persons with incident CHF and AMI. Moreover, data on risk factors are customarily collected after diagnosis. However, in the present paper, we present data on pre-morbid assessed risk factors.

Methods

Groningen longitudinal aging study

Detailed description of data collection is published elsewhere (Kempen et al., 1997a,b, 1998; Ormel et al., 1997). Briefly, the study population comprised 8723 persons aged 57 and older on January 1st 1993, who were registered as patients with the 27 general practitioners participating in the Morbidity Registration Network Groningen. 152 persons died or left the practice by the time contact was initiated. Useful baseline data were available for 5279 subjects (62%; 5279/8723–152).

Incident CHF or AMI

From 1993 until January 1st, 1998, all patients with a new post-baseline episode of AMI or diagnosis of CHF according to the criteria of the International Classification of Primary Care were identified by general practitioners (Lamberts and Wood, 1987). AMI was diagnosed if two of the following three symptoms were present: chest pain characteristic of myocardial ischemia lasting more than 15 min, abnormal ST-T changes or Q waves on an electrocardiogram, or elevation of blood cardiac enzymes. CHF was diagnosed if three of the following five symptoms were present: dependent edema, raised jugular venous pressure or hepatomegaly in the absence of liver disease, signs of pulmonary congestion or pleural effusion, enlarged heart, or dyspnoea in the absence of pulmonary disease.

During the enrolment period (1993–1998), 198 patients with a new episode of AMI and 274 patients with a first diagnosis of CHF after baseline were recruited. Cases with both diagnoses in the enrolment period (N=28) were included according to the first diagnosis. The study protocol was approved by the Medical Ethical Committee of the University Medical Centre Groningen.

Mortality

Survival was ascertained for all patients on June 1st 2001 using municipal registrations. All-cause mortality was included in this study. For several reasons, it is more relevant to study all cause mortality in a community-based older population as ours. Classification of causes of death always involves a subjective component (Gottlieb, 1997). Moreover, most older persons die as a consequence of a combination of factors, and the recorded cause of death may be less explanatory in older than in younger persons (Fried et al., 1998).

Risk factors for mortality

Risk factors are assessed during the baseline assessment in 1993, i.e., prior to the cardiac diagnosis.

Demographic risk factors include: gender, age, marital status (living with versus without a partner) and educational level (high versus low).

Baseline health status includes comorbidity, physical functioning, and self-rated health. Comorbidity is assessed with total number of 19 chronic medical conditions. In order to reduce report bias, only those conditions in the 12 months prior to the interview that required a GP or specialist consult and/or prescription of medicine were counted, which was found to be valid (Kriegsman et al., 1996).

In addition the presence of hypertension and diabetes mellitus are analyzed separately.

Physical functioning was assessed with the Groningen Activity Restriction Scale (GARS), comprising 18 ADL (activities of daily living) and IADL (instrumental activities of daily living) items, each with four response categories. Scores may range from 18 (no physical dysfunction) to 72 (maximum level of physical dysfunction). Results of previous studies show that GARS meets the stochastic cumulative scalability criteria of the Mokken Model (Kempen et al., 1996; Kempen and Suurmeijer, 1990).

Self-rated health is assessed with a 1-item question: “how do you rate your overall health” (Miilunpalo et al., 1997). Scores were classified in two categories due to skewed distribution: 0 (excellent, very good, good), 1 (fair, bad).

Potentially modifiable risk factors include: smoking, Body Mass Index (BMI) and depression. Smoking behavior was assessed by a self-report questionnaire and defined in two classes: (0) never smoked cigarettes or cessation of smoking more than 10 years ago, and (1) current smoker or cessation of smoking less than 10 years ago. BMI was calculated as weight (kg) divided by the square of height (m²) (both self-report), and categorized using cut-offs recommended by the World Health Organization: normal weight (18.5 to <25), overweight (25 to <30) and obese (≥30) (World Health Organization, 1998). Three underweight cases (BMI<18.5) were excluded.

Depressive symptoms were assessed with the Hospital Anxiety and Depression Scale (HADS) (Spinhoven et al., 1997; Zigmond and Snaith, 1983). HADS has been validated for an older Dutch population (Spinhoven et al., 1997). Due to a skewed distribution, depression scores were dichotomized using a standardized cut point: 7 or lower (non-case) and 8 or higher (possible case) (Bjelland et al., 2002; Spinhoven et al., 1997; Zigmond and Snaith, 1983).

Analyses

Risk factors for mortality are analyzed for CHF using 8 year follow-up. In AMI patients, predictors for short-term mortality (within 1 month) and longer term mortality are analyzed separately. First, univariate hazards (odds ratios) associated with each risk factor were examined. Second, multivariate Cox proportional hazard analyses were performed with a stepwise forward conditional method including all potential risk factors. Finally, interactive (effect modification) between all risk factors and gender was tested with two-way product terms. Each interaction term (and the single risk factor, if not yet in the model) was successively added to the multivariate model to evaluate
possible interaction effects with gender. A p value of <0.05 was considered statistically significant. Analyses are performed with SPSS for windows version 12.

**Results**

Table 1 shows the prevalence of risk factors at baseline among males and females for both patient groups. Several risk factors are more pronounced among females, while smoking is more prevalent among male patients. Survival rates at several intervals are presented in Table 2.

**Risk factors for mortality among persons with CHF**

Table 3 shows the results of the Cox proportional hazard analyses among persons with CHF. At a univariate level, higher age, living without a partner, diabetes mellitus, high physical disability and low self-rated health are significantly related to mortality, but gender is not. Because several risk factors are more pronounced among females, while smoking is more prevalent among males, gender effects may be magnified or overlooked in univariate analyses. The multivariate model reveals five significant risk factors: male gender, higher age, smoking, diabetes mellitus and physical disability. This multivariate model shows that male gender is associated with a 1.7 increased mortality risk, after adjusting for the other four significant risk factors.

None of the two-way interaction terms of risk factors with gender is significant. However, additional multivariate analyses (not shown) indicated that smoking tended to be associated with a 1.9 significant increased risk among males (95% CI: 1.2, 3.0) but not among females (adjusted OR = 1.2, 95% CI: 0.6, 2.2). Similarly, the multivariate adjusted risk associated with diabetes mellitus was 2.4 (95% CI: 1.4, 4.2) in females and non-significant among males (adjusted OR = 1.6, 95% CI: 0.8, 3.0). Additional analyses on the other risk factors did not show such gender differential effects. However, the gender-specific effects of smoking and diabetes should be interpreted with caution, since the interaction terms were not significant (P = 0.227 and P = 0.324).

**Risk factors for short-term and longer term mortality among persons with AMI**

Table 4 shows the predictors for short-term (57 patients died within 1 month) and longer term mortality (37 died after 1 month) among persons with AMI. Again, gender is not related to mortality in univariate analyses. Multivariate analyses showed higher age and lower BMI to be related to short-term mortality. After adjustment for other risk factors, male gender is associated with a 3.2 increased mortality risk on longer term. In
addition to male gender, higher age and diabetes mellitus predict longer term mortality. The interaction of gender and diabetes was borderline significant ($P < 0.10$); diabetes mellitus tended to be a significant risk factor among females (adjusted OR = 7.4, 95% CI: 2.0, 26.6) but not among males (adjusted OR = 2.4, 95% CI: 0.9, 6.3).

Additional multivariate analyses, revealed male gender (OR = 1.9, 95% CI: 1.1, 3.1), older age (OR = 1.7 per decade, 95% CI: 1.3, 2.3), normal BMI (OR = 0.5, 95% CI: 0.3, 0.8 for overweight; OR = 0.4, 95% CI: 0.1, 0.9 for obese), and diabetes among females (OR = 2.8, 95% CI: 1.3, 6.2) as predictors for total (short- and longer term) mortality in persons with AMI (data not shown).

### Gender-specific mortality rates

In Fig. 1, the survival functions belonging to the multivariate Cox models show the effects of gender. Male gender is

associated with a 1.7 increased mortality risk in CHF and a 1.9 increased mortality risk in AMI (combining short-term and longer term mortality).

Discussion

One of the most striking findings was that in this sample, gender was a lurking variable (Joiner, 1981) predicting mortality for both CHF and AMI. Namely, in neither case did gender predict mortality in a simple univariate association; instead, being male emerged for both conditions as a strong predictor of mortality only in multivariate analyses taking into account other classic risk factors.

We had postulated two broad strategies for explaining gender differences in mortality. The first focuses on differences in the prevalence of risk factors. We have demonstrated that the excess in mortality risk in males is not due to higher prevalence of other risk factors (such as smoking). In fact, most risk factors are more pronounced in females than in males.

The second explanation is that risk factors may have differential effects for males and females. Our results show indeed a differential effect of diabetes mellitus, which was a significant risk factor for longer term mortality among females with AMI but not among males with AMI. This gender-specific effect has been described earlier (Crowley et al., 2003; Lee et al., 2000), and suggested explanations include HDL cholesterol, estrogens, coagulation, patterns of obesity, or hyperinsulinemia (Lee et al., 2000) and lower use of effective cardiac medications in female than male diabetics (Crowley et al., 2003). The discussion of these theories and others is beyond the scope of this article; suffice to say that the underlying basis for the gender differences in risk from diabetes remains, for the most part, speculative. In addition, data suggest differential effect of smoking, which may be more relevant in male than in female patients. Gender differences in sensitivity to smoking has been reported, showing that males are more affected by smoking (i.e. higher mortality risks) than females (Marang-van de Mheen et al., 2001). Thus, risk factors for mortality showed few, albeit interesting, differences between males and females.

Mortality risk could thus be predicted by six characteristics: two demographic (high age and male gender), two health behavioral (low BMI and smoking), and two health parameters (diabetes mellitus and physical disability). In our elderly population, higher BMI was related to lower short-term mortality rates for AMI. These seemingly paradoxical finding might be seen in contrast with the literature on obesity as a robust risk factor for mortality (Fontaine et al., 2003). However, there is some consistency in findings that higher pre-existing BMI is actually associated with lower risk for mortality (Curtis et al., 2005; Eisenstein et al., 2005). In older age, a lower BMI might be a parameter of worse overall health, chronic disease like cancer, a disturbance of the metabolic system, worse eating habits or an indicator of physical infirmness. Another possible explanation relates to selective survivors, indicating that vulnerable overweighed people have died in earlier life and that the overweighed people in our older cohort represent a strong subgroup of overweight people. These indirect explanations are of particular interest since we found lower BMI to be a predictor of short-term mortality but not on longer term.

There is a large literature concerning mortality associated with depressive symptoms (Van Melle et al., 2004; Wulsin and Singal, 2003). Our results do not show any effect of depressive symptoms on mortality. One of the differences between our study with those finding an effect of depression is that depressive symptoms were assessed prior to diagnosis, not post-morbid. A post-morbid depression may be different from pre-morbid depression, and effects may differ with time (Barefoot et al., 1996).
Taken together, gender differences in the prevalence of risk factors and differential effects of these risk factors are relevant in examining the gender gap in mortality, but do not explain the increased mortality risk among male patients with CHD. Other factors thought to explain this gender gap include genetics, sex hormones, the pathophysiological origin and expression of CHF and AMI (Barrett-Connor, 1997). Furthermore, the gender gap may be related to differences in referral and therapeutic management (Bouma et al., 1999; Maynard et al., 1997). However, these differences all favor male patients and are therefore no help to explain the increased mortality rates for males. The increased mortality risk among males with CHD may also relate to overall worse survival among males in the general population. Females, who represent the majority of elder persons, have a higher life expectancy than males but they also experience a longer disabled life than males. The better survival of females has often been related to the protective role of estrogens (Isles et al., 1992). The role of estrogens has been related to cholesterol and also to the earlier discussed gender differential effect of diabetes, but may be less important in older (postmenopausal) women. Clearly, much interesting theories to explain the gender gap in mortality of CHD patients exist, and these theories are most definitely not mutually exclusive and research integrating several theories may be most relevant in explaining the gender gap.

Study strengths and limitations

In this study, risk factors were assessed prior to the cardiac diagnosis and this has several advantages, including that all incident cases in the cohort could be analyzed. This included also patients who died shortly after diagnosis and patients who would not give consent to participate in a study once they were diagnosed. These groups of patients are missed in studies that rely on data collection after diagnosis.

We demonstrated that the gender gap in mortality is not accounted for by other classic risk factors. Although we have included many risk factors, it can be that imbalances in the occurrence of other (unknown) risk factors related to gender are important.

Although our study included 472 patients with CHD, the power of our analyses may be limited since analyses are performed in subgroups according to the original diagnosis and included many different risk factors. Nevertheless, our results gain weight in presenting results for CHF and AMI separately, since identifying risk factors for specific diseases helps us understand the pathways which originate the risks.

Conclusions

Mortality is increased among males with CHF or AMI, compared to female patients. Risk factors for mortality in newly diagnosed patients are predominantly similar for males and females, except for diabetes which is a risk factor among females but not among males. Female cardiac patients with diabetes mellitus are a particularly high-risk group in need of targeted treatment strategies and enhanced lifestyle changes.

Acknowledgments

This research is part of the Groningen Longitudinal Aging Study (GLAS). GLAS is conducted by the Northern Centre for Healthcare Research and various Departments of the University of Groningen in the Netherlands. The primary departments involved are Public Health and Health Psychology, Family Medicine, Psychiatry, Sociology (ICS) and Human Movement Sciences. GLAS and its substudies are financially supported by the Dutch government (through NESTOR), the University of Groningen, the Faculty of Medical Sciences, the Dutch Cancer Foundation (NKBIKWF), and The Netherlands Organization for Scientific Research (NWO).
