Received 23 December 2009/Accepted 12 March 2010

In plants and animals, cryptochromes function as either photoreceptors or circadian clock components. We have examined the cryptochrome from the filamentous fungus *Neurospora crassa* and demonstrate that *Neurospora cry* encodes a DASH-type cryptochrome that appears capable of binding flavin adenine dinucleotide (FAD) and methenyltetrahydrofolate (MTHF). The cry transcript and CRY protein levels are strongly induced by blue light in a *wc-1*-dependent manner, and cry transcript is circadianly regulated, with a peak abundance opposite in phase to *frq*. Neither deletion nor overexpression of *cry* appears to perturb the free-running circadian clock. However, *cry* disruption knockout mutants show a small phase delay under circadian entrainment. Using electrophoretic mobility shift assays (EMSA), we show that CRY is capable of binding single- and double-stranded DNA (ssDNA and dsDNA, respectively) and ssRNA and dsRNA. Whole-genome microarray experiments failed to identify substantive transcriptional regulatory activity of *cry* under our laboratory conditions.

Cryptochromes (CRY) are defined as proteins that share sequence similarity with the DNA-repairing enzyme photolyase but lack conventional photolyase activity (45, 58, 59). Phylogenetic analysis of cryptochrome sequences indicates three general classes: plant cryptochromes, animal cryptochromes, and DASH-type cryptochromes (46). Structurally, most cryptochromes have an amino-terminal photolyase-related region (PHR) and a carboxyl-terminal domain. However, the carboxyl-terminal domain is missing in DASH-type cryptochromes (46). In *Arabidopsis thaliana*, *cry1* and *cry2* encode cryptochromes required to mediate the entrainment of the circadian clock, as well as expression of a variety of light-induced genes and developmental processes (31, 48, 62, 72). In contrast, *Arabidopsis cry3* is a DASH-type cryptochrome and appears to have a photolyase activity specific to single-stranded or looped duplex DNA (55, 58, 59). Animal cryptochromes serve functions similar to those of their plant counterparts—acting as either photoreceptors or components of circadian clocks (46). For instance, in *Drosophila*, *cry* is a blue-light photoreceptor (21, 63). Once light activated, CRY facilitates resetting of the clock by mediating the light-dependent degradation of TIM (7). In contrast, mammalian *cry* appears to play no role in circadian photobiology but instead is an integral part of the negative feedback loop of the clock (43). Light-dependent and -independent effects of animal *cry* on the regulation of the circadian clock have been well documented for both *Drosophila* and mice (30, 40, 60, 68). In addition to its widespread clock functions, animal *cry* has been shown to mediate light-dependent magnetosensitivity in *Drosophila* (27).

*Neurospora crassa* has served as a model organism to study the circadian clock and light responses in eukaryotic cells for several decades (13, 19, 34, 35, 56). Two GATA family zinc finger transcription factors, white collar-1 (WC-1) and white collar-2 (WC-2), form an obligate heterodimer (WCC) via their Per-Arnt-Sim (PAS) domains that acts both as the photoreceptor for light responses/clock resetting and, in the dark, as a transcription factor complex that promotes the expression of FRQ, a core clock component analogous to PER/CRY in mammalian clock systems. WC-1 shares extended sequence and functional similarity with one of the heterodimeric activators in the mammalian feedback loop, BMAL1 (brain and muscle Arnt-like protein-1) (44); in the feedback loop, WCC drives expression of FRQ, which then feeds back to repress the activity of its activator, WCC, resulting in closure of the negative feedback loop (19). WC-1 is also a flavin adenine dinucleotide (FAD) binding protein capable of sensing light. For light responses, WCC activates downstream target genes through recognition of the light-responsive elements (LREs) (9, 23) in the promoters of target genes and activation of another light-responsive transcription factor, *sub-1*, to activate late light responses (8). In the absence of WC-1 or WC-2, most early and late light responses are lost, suggesting their dominant roles in mediating light signals in *Neurospora*. Notably, despite extensive efforts in several labs to identify blind strains, only *wc-1* and *wc-2* mutants have been repeatedly isolated (47). However, unexpectedly, the completion of the *Neurospora* genome sequencing revealed the presence of an additional putative blue-light photoreceptor, cryptochrome (*cry*), based on its sequence similarity to known *cry* genes (25). Given the
regulatory similarities in the molecular basis of the circadian feedback loop and light signaling cascades among different model systems, we were interested in characterizing the clock and light functions of this novel cry at the molecular level.

We show that Neurospora CRY shares a high level of sequence similarity and domain structure with other DASH-type members, including FAD and MTHF (methylenetetrahydrofolate) binding sites as well as the residues potentially interacting with cyclobutane pyrimidine dimers (CPDs). Spectral analysis with purified CRY verified the interactions with FAD and MTHF. Like other photoreceptors in Neurospora, the transcript and protein levels of cry are highly induced by light in a wild-type-dependent manner. Meanwhile, we found that the transcript of cry in the dark is under circadian clock control, with peak expression antiphase to frq, while the protein level becomes quickly dampened after 12 h in darkness. Race tube analysis with the knockout strains suggests that Neurospora cry is not a clock component insofar as its loss does not change the free-running period of the circadian rhythm; however, an alteration of the light-entrained phase is noted in cry mutant strains. Interestingly, Neurospora CRY is capable of binding single- and double-stranded DNA and RNA in vitro, as demonstrated by electrophoretic mobility shift assays (EMSA). However, whole-genome microarray analysis indicates that both early and late transcriptional light responses remain unaltered in the absence of cry. Thus, although the explicit signal transduction pathway that CRY impacts is unclear, we show that its loss affects the phase of entrainment of the circadian clock by light.

MATERIALS AND METHODS

Strains. The N. crassa strains used were 343-25 (ras-1/3D cry/hph), with 328-4 (ras-1/3D) as the corresponding ras-1/3D cry' strain, and 378-5 (cry/hph), with 378-6 as the corresponding wild-type (WT) strain. 378-5 and 378-6 are sibling progeny from a cross of 343-25 with N. crassa wild-type FGSC 2489 (OR74A). For circadian entrainment experiments, an independently but almost identically produced knockout strain was used. The 5' and 3' untranslated regions (UTRs) of NCU005823 (cryptochrome) were amplified with 5' CGTGCCTCTTCACACTT GAG3' (forward) and 5' CGTGGCAACAGGTAGAAG3' (reverse) and with 5' GGCGGTCCITACACGGCTG3' (forward) and 5' CGGGGCCGCTCCTG TCAAAATC3' (reverse), respectively. The byrgmycin resistance encoding bpcl was amplified from plasmid pAF67 (25) with 5' GATGAAATTG GATG TATTG (forward) and GAGTTCTAGAT AAAGAAGGATTACCTC (reverse). Blunt-end ligations were followed by restriction digestion and subsequent PCR amplification yielded fragments consisting of 5' UTR-hph and hph-3' UTR. An additional PCR step using primers within the hygR cassette, hsm-1 (5' CGTGCCTCG GTGAGTTCAAGGATTTT3') together with the 3' UTR reverse primer and hsm-r (5' TGCCCTGGTCCAGTCAATGACC3') (both sequences from H. Colot [personal communication]) together with the 5' UTR forward primer, generated two fragments with a ca. 600-bp overhang within the hph-encoded hygR cassette. These were gel purified and cotransformed into ras-1/3D (FGSC 1489), where they underwent homologous recombination. Strains selected for byrgmycin resistance were verified for correct insertion by PCR, restriction digests, and sequencing. Homokaryons were produced by microconidiation and hygromycin selection. Strains were named on the basis of their parent as well as the marker(s) used. The majority of the six-His-tagged CRY polypeptide was in the inclusion body fraction.

Targeted disruption of cry and cry-overexpressing strain. Construct pAF67 was generated in which the 5' and 3' sequences flanking the CRY open reading frame (ORF) were appended to the byrgmycin B phosphotransferase (hph) coding region, whose expression was driven by the Aspergillus nidulans trpC promoter, thus allowing selection by hygromycin B resistance. pAF67 was transformed into N. crassa, and byrgmycin-resistant transformants containing single homologous integrations of the DNA were backcrossed to the wild type (WT) to obtain homokaryotic disruption strains (343-25), as judged by DNA gel blot analysis of genomic DNA (data not shown). Because the annotation of the N. crassa genome was incomplete when 343-25 was made, the disruption retained the first exon but spanned the entire second exon, including all chromophore binding sites. The pAF67 construct, similar to those described by Larrondo et al. (42), was used for overexpressing CRY in Neurospora and contains the quinone-2 (qa-2) promoter and 5' UTR followed by a copy of the genomic region spanning the CRY ORF and then the Aspergillus nidulans trpC 3' UTR in a his-3 targeting vector. The qa-2 promoter enables regulated gene induction by the addition of quinic acid. pAF67 was transformed into N. crassa strain 87-74 (ras-1/3D his-3) following standard transformation protocols so that the overexpression of cry mRNA, confirmed to be approximately 25-fold (as determined by quantitative RT-PCR, n = 3; data not shown), is driven from a transgene at the his-3 locus.

Culture conditions and light treatment. The general conditions for growth and light manipulations are described elsewhere (8, 16). Liquid culture and race tube experiments were performed as previously described (1, 14, 24) except those with the CRY overexpressor strain, which used a modified growth medium containing 1 X Vogel's medium, 0.17% arginine, 50 mg/ml biotin, 1.5% Bacto agar, and 0.015 M quinic acid. For the expression analysis of cry and frq following light exposure, cultures were irradiated with ~40 μmol photons/m2/s of white light (GE F20T12-CW cool white fluorescent light bulb) for the indicated durations, following 20 h of dark incubation. Red-, red-, and blue-light experiments were performed using an E-30LED growth chamber equipped with red (660 nm), blue (450 nm), and blue-enhancing diodes (Perceval Scientific, Inc., Perry, IA). For the dark-grown samples, an arbitrary “direction” was chosen that its loss affects the phase of entrainment of the circadian rhythm; however, an alteration of the light-entrained phase is noted in cry mutant strains. Thus, although the explicit signal transduction pathway that CRY impacts is unclear, we show that its loss affects the phase of entrainment of the circadian clock by light.
protein was purified by nickel chelate affinity chromatography using Ni-nitrito-
triacetic acid (Ni-NTA) Superflow agarose (Qiagen) according to the manufact-
urer's directions. The eluate was dialyzed against phosphate-buffered saline

Results
Neurospora CRY has conserved chromophore binding sites for FAD and MTHF as well as residues for interacting with
CPDs. CRY (encoded by gene NCU00582.4) is predicted to be a
722-amino-acid protein expressed from a 2,956-nucleotide (nt) transcript having one intron (Fig. 1A). Based on the phylo-
genetic analysis of the chromophore family across different
species, CRY is categorized as a DASH-type cryptochrome (46), most similar to those found in bacteria, plants, and ani-
(15, 46). Given that Arabidopsis thaliana cry3 (Atcry3) is one of the best-characterized members in this family, we
aligned the amino acid sequence of Neurospora CRY (XP_965722) with that of AtCRY3 (NP_568461), together with
two of those other DASH-type members from Xenopus (XicCRY-DASH, NP_001084438) and zebrafish (DrCRY-
NP_991249), to check the integrity of its functional regions. Overall amino acid similarity between Neurospora
CRY and AtCRY3 is about 44%, with a very low E value (4e-53, NCBI BLASTP). Of 16 amino acids which act in bind-
ing FAD in AtCRY3 (marked by black asterisks in Fig. 1) (5), 15 are conserved in CRY. In addition, four of the five residues
(E129, E130, E459, and Y465, marked by green asterisks in Fig. 1) essential for hydrogen bonds with methenyltetrahydro-
folate (MTHF) (37) are identical across the four species, sug-
any other predicted members of the photolyase/cryptochrome
family. The crystal structure study of AtCRY3 predicts six residues to directly interact with CPD-containing DNA (37); these are identical across the four species, sug-
functioning as a cryptochrome family member. A two-class unpaired test was performed with a
Significance analysis of microarrays (SAM). Microarray data from the wild-
type strain were used as class I (n = 3) in contrast to class II, the data from the
cryptochrome knockout strain. A two-class unpaired test was performed with a
t-statistic method. Missing data were imputed via a k-nearest neighbor algorithm
(6 = 10) before permutations (n = 100) for estimating the false discovery rate
(FDR).

RESULTS
Neurospora CRY has conserved chromophore binding sites for FAD and MTHF as well as residues for interacting with CPDs. CRY (encoded by gene NCU00582.4) is predicted to be a 722-amino-acid protein expressed from a 2,956-nucleotide (nt) transcript having one intron (Fig. 1A). Based on the phylogenetic analysis of the chromophore family across different species, CRY is categorized as a DASH-type cryptochrome (46), most similar to those found in bacteria, plants, and animals (15, 46). Given that Arabidopsis thaliana cry3 (Atcry3) is one of the best-characterized members in this family, we aligned the amino acid sequence of Neurospora CRY (XP_965722) with that of AtCRY3 (NP_568461), together with two of those other DASH-type members from Xenopus (XicCRY-DASH, NP_001084438) and zebrafish (DrCRY-DASH, NP_991249), to check the integrity of its functional regions. Overall amino acid similarity between Neurospora CRY and AtCRY3 is about 44%, with a very low E value (4e-53, NCBI BLASTP). Of 16 amino acids which act in binding FAD in AtCRY3 (marked by black asterisks in Fig. 1) (5), 15 are conserved in CRY. In addition, four of the five residues (E129, E130, E459, and Y465, marked by green asterisks in Fig. 1) essential for hydrogen bonds with methenyltetrahydrofolate (MTHF) (37) are identical across the four species, suggesting that Neurospora CRY might bind FAD and MTHF in a manner similar to that of other members in the DASH-type family. The crystal structure study of AtCRY3 predicts six residues to directly interact with CPD-containing DNA (37); these are identical across the four species, suggesting that Neurospora CRY might also interact with DNA (55, 59) in a manner similar to that of AtCRY3. In addition to the DNA/FAD binding domains which constitute the N-terminal two-thirds of the protein, CRY contains an ~200-amino-acid C-terminal region rich in glycines (Fig. 1A) not found in any other predicted members of the photolyase/cryptochrome family.

To find out if the Neurospora CRY could function as a photolyase in vivo, a disruption mutant strain of cry (343-25) was tested for photoreactivation. In the WT strain, increasing exposure to UV irradiation results in decreased survival, while light treatment following UV exposure increases survival of the WT due to the activation of DNA-repairing photolyase (Fig. 1C). With light treatment following UV irradiation, the sur-
FIG. 1. *Neurospora* CRY has conserved chromoprobe binding sites for FAD and MTHF as well as residues for interacting with CPDs and does not have photolyase activity. (A) The sequence for *Neurospora* CRY encoded by NCU00582.4 (http://www.broadinstitute.org/annotation/genome/neurospora/GeneDetails.html?sp=H11005S7000004871288104) was aligned with AtCRY3 (NP_568461), and two other DASH-type cryptochromes from *Xenopus* (XlCRY-DASH, NP_001084438) and zebrafish (DrCRY-DASH, NP_991249), using MUSCLE software (20). Asterisks point to amino acids essential for FAD (black) and MTHF (green) binding. Conserved CPD-interacting residues are marked by red asterisks. The highlighted (red) box indicates the unique RGG repeats in *Neurospora* CRY. (B) Phylogenetic analysis of the photolyase/cryptochrome family. Protein
vival of 343-25 was restored to the same level as in the wild-type strain, suggesting that the photolyase activity is undamaged in the absence of CRY. In contrast, as an internal control for the assay, a loss-of-function mutant strain of the previously characterized *Neurospora* CPD photolyase (61), *phr* RIP, showed no sign of increased survival with light treatment, suggesting a total lack of photoreactivation in this strain. The *phr* gene appears to encode the only photolyase in *Neurospora*, and CRY, lacking any detectable photoreactivation activity at least under these assay conditions, would be by definition a cryptochrome.

**Bacterially expressed *Neurospora* CRY is a FAD and MTHF binding protein.** To empirically test whether *Neurospora* CRY binds FAD and MTHF, CRY was expressed and purified in *Escherichia coli* using a six-His tag and Ni-NTA affinity chromatography. A small proportion of the expressed protein was soluble, allowing purification of CRY under nondenaturing conditions with its associated cofactors as shown in Fig. 2A. Fractions containing CRY appeared yellow, supporting that CRY binds a flavin (59). The CRY absorbance spectrum exhibited a major peak at 375 nm, two minor peaks at 445 and 470 to 472 nm, and a tail extending out to 600 nm (Fig. 2B). The dominant peak at 375 nm suggests the presence of MTHF (49); the two smaller peaks indicate the presence of fully oxidized FAD (445 nm) and flavin neutral radical (FADH$_0$, 470 to 472 nm) (3, 37). Notably, the absorption spectrum of CRY is

sequences of members of the photolyase/cryptochrome family were retrieved from the NCBI database. A multiple sequence alignment was constructed with Lasergene MegAlign software using the Clustal method with the Identity residue weight table. Similar phylogenetic trees were generated using either the Structural or PAM100 residue weight tables (not shown). (C) Photoreactivation analysis of the WT (378-6), *cry*-disruptant (378-5), and *phr* RIP strains. Each strain was irradiated by UV light at the indicated doses and plated onto two petri plates. One plate was exposed to fluorescent light for 60 min (photoreactivation [PR]) and the other received no light treatment.
almost identical to the spectra of Atcry3 shown to bind FAD and MTHF (37). To confirm the flavin moiety, the bound cofactors were released from CRY by a chloroform extraction method and the fluorescence spectrum was recorded. Measurement of the excitation at 450 nm resulted in fluorescence emission with a maximum at 522 nm that was 3.5-fold higher at pH 2.0 than at pH 7.4 (Fig. 2C). This emission peak is indicative of a flavin moiety, and the increase in fluorescence intensity with decreased pH identifies FAD as the specific flavin derivative (70). A thin-layer chromatography (TLC) assay further confirmed one of the released cofactors to be FAD (Fig. 2D). Overall, our spectral analysis data support that the purified *Neurospora* CRY was loaded with FAD and MTHF, as predicted by the sequence analysis.

*Neurospora* cry transcript and protein levels are both strongly induced by light in a wc-1-dependent manner. To determine if the cry gene is regulated by light, Northern blot analysis was performed on RNA isolated from fungal mycelia. A 30-min white-light treatment resulted in a dramatic increase in cry transcript levels relative to a dark-grown sample (Fig. 3A). The light-induced cry transcript ran at approximately the same position as the smallest *Neurospora* rRNA species, indicating that the cry transcript is approximately 2 kb, in agreement with the cDNA analysis. Light failed to induce cry transcript levels in a WC-1 mutant (wc-1<sup>ER53</sup>), suggesting that WC-1 is the photoreceptor/transcription factor responsible for the light regulation of cry transcription. Using blue-, red-, or far-red-light-emitting diodes (LEDs) as the light source, only blue-light treatment resulted in an increase in *Neurospora* cry transcript levels (Fig. 3B). WC-1 is responsive to blue-light wavelengths but not to red or far-red light, consistent with WC-1 being the photoreceptor directly responsible for the light
induction of cry. Further quantification was performed using RT-QPCR. A wild-type strain was subjected to increasing doses of white light for 15 min to 24 h. The cry transcript was rapidly and highly induced, reaching levels 200- to 300-fold higher than levels found under dark conditions within 15 to 30 min (Fig. 3C). The cry transcript levels declined following the initial peak due to photoadaptation but remained elevated approximately 50-fold higher than dark levels after 24 h in constant light.

To detect CRY protein levels and study its regulation, we generated antiserum against the full-length CRY protein. Western blot analysis of extracts from the WT and Δcry strains demonstrated the specificity of the antiserum (Fig. 3D). The antibody recognized two proteins: one was nonspecific, and a single specific protein band was detected in the WT extracts, but not in the disruption mutant (343-25) extracts, at the approximate predicted molecular mass of CRY (80 kDa). CRY was present at very low to undetectable levels in the dark but was detectable following as little as 30 min of light treatment (Fig. 3D). The CRY protein levels continued to increase, reaching a peak between 4 and 8 h, and then remained elevated under constant light exposure (Fig. 3D and E). Although both the transcript and protein levels remain elevated under constant light, the profiles differ slightly, with transcript levels rapidly peaking at 15 to 30 min and protein levels lagging by several hours.

Neurospora cry transcript is rhythmically expressed and antiphasic to frq but dispensable for the circadian clock. The transcript levels of cry genes from organisms, including Arabidopsis, Drosophila, and mouse, are circadianly regulated, with amplitudes of less than 3-fold (21, 33, 41, 51, 66). To test for circadian regulation of the cry transcript, mycelial tissue of Neurospora was collected at different developmental stages and subjected to RT-QPCR. A wild-type strain was subjected to increasing doses of white light for 15 min to 24 h. The cry transcript appeared to be circadianly regulated (F_{0.05} = 2.27; P = 0.05), with levels decreasing following the light-to-dark transfer, reaching a trough after ~12 to 16 h followed by an increase reaching a peak after a total of ~20 to 24 h in the dark. The cry transcript oscillated with an ~2-fold amplitude but at levels well below those seen in the light (i.e., time zero in Fig. 3C is equal to 20 h in Fig. 4A). Notably, in Neurospora, where most clock-regulated genes are morning specific (12), including frq, cry appears to be an evening-specific gene. Meanwhile, CRY protein levels remained elevated for the first 12 h but then decreased to low/undetectable levels by 16 h with no subsequent increase detected, as shown in Fig. 4B. In this regard, CRY is similar to the Neurospora photoreceptor VVD, which regulates photoadaptation and thereby acts to modify the primary biological response elicited by the WCC. As a positive control, FRQ abundance and phosphorylation patterns were seen to oscillate in a circadian manner as previously described (26). Although CRY does not appear to be circadianly regulated, it is possible that CRY is fluctuating at very low levels, similar to what is found in the cry transcript.

To determine whether cry plays any role in the Neurospora circadian system, the WT strain, a cry disruption strain (343-25), and a strain overexpressing cry (cry^{OX}; see Materials and Methods) were grown in race tubes as described previously (19). Strains 343-25 and cry^{OX} had periods (22.15 ± 0.07 h and 22.77 ± 0.11 h, respectively) similar to that of the WT (22.44 ± 0.11 h; data not shown) in constant darkness, indicating that the cry gene is not a core clock component. In addition, light induction of frq, a mechanism by which light input resets the clock (14), was also unaltered in strain 343-25, suggesting that cry is not involved in light signaling to the clock (data not shown). Using a temperature step-up from 4°C to 25°C (in constant darkness) to reset the race tube cultures also resulted in a WT period for strains 343-25 and cry^{OX} (data not shown).

We then investigated synchronization of the circadian clock to zeitgeber cycles, a protocol that yields a strain-specific phase relationship between endogenous (circadian) and exogenous cycles, an active process called entrainment. (Zeitgebers [from
the German for “time-givers”) are environmental stimuli that alter the phase of a biological clock; light and temperature are common examples.) In temperature cycles of 22°C to 27°C, ΔcryCM resembled the wild-type strain (data not shown). That is, conidiation occurred at the same phase of the temperature cycle for both the mutant and the wild type. However, in light cycles (with incubations in light followed by darkness), a delay in conidiation (interpreted as a delay in entrained phase) was observed in the absence of CRY (Fig. 5). In general, when white light was used, longer photoperiods yielded larger phase delays (e.g., 50 min at a light/darkness cycle [LD] of 12 h of light/12 h of darkness [12:12] versus 2 h at LD 18:6; Fig. 5A and 5B). An additional protocol for entrainment of circadian rhythms is that of skeleton photoperiods, which calls for delivering a light pulse at either end of a dark incubation. This procedure often mimics full photoperiod entrainment, suggesting that the lights-on and lights-off signals play a dominant role in entrainment. When we replaced dawn and dusk by 2-h light pulses (LD 2:10:2:10), the phase of entrainment of the ΔcryCM strain was delayed by 3 h compared to that of the wild-type strain (Fig. 5C).

_Neurospora_ CRY binds to DNA and RNA. In addition to the interaction with the CPD-containing DNA, DASH-type members from _Arabidopsis thaliana_ (39) and _Synechocystis_ sp. strain PCC6803 (5) have been shown to bind to double-stranded DNA nonspecifically, although the functional significance of this binding is not yet understood. We tested CRY’s ability to bind to DNA using bacterially expressed CRY in electrophoretic mobility shift assays (EMSA). The use of GST-CRY in a binding reaction also resulted in the following increasing amounts of CRY: 0, 0.0625, 0.125, 0.25, 0.5, 1, and 2 μg.

![Figure 5](image-url)

**FIG. 5.** Entrained phase of ΔcryCM is delayed in light cycles. Race tubes were subjected to 24 h cycles with various amounts of light (L) and darkness (D). The tubes were scanned, and the locations of the conidial bands within the light/dark cycle were graphed as increased pixel density. (A) Six days of conidiation are shown (black tracings), averaged from results for three (LD 8:16) to six (LD 12:12 and LD 16:8) race tubes. The relative positions of conidiation and the LD cycle are graphed, with the gray rectangles representing darkness and the open rectangles representing light. (B) The phase information (onset of conidiation) for a series of photoperiod experiments is graphed. Filled circles are wild-type results; open squares are the ΔcryCM results with error bars (frequently smaller than the symbol) representing SEM. Phase estimates are based on analysis of between 5 and 14 race tubes per entrainment condition. (C) Race tubes were incubated in a skeleton photoperiod of LD 2:10:2:10, shown as open rectangles (light) and gray rectangles (darkness). The position of conidial bands (black peaks) is later in the mutant strain.
a decreased migration of the DNA (Fig. 6B, lane 3), and more importantly, the GST-CRY reaction had a greater decrease in mobility of the DNA (compare lanes 2 and 3) due to the mass increase of the GST tag. GST alone did not bind to the DNA (lane 4). As an additional control, we cleaved CRY from GST and used this cleaved CRY in a binding reaction which resulted in a decrease in migration of the DNA (lane 5) similar to the HIS-CRY reaction. Taken together, these results indicate that *Neurospora* CRY is capable of binding to double-stranded DNA *in vitro*. Meanwhile, CRY appears to bind to DNA in a non-sequence-specific fashion, because binding reactions using DNA probes of different sequences produced similar results and addition of unlabeled DNA of unrelated sequence to the binding reactions resulted in decreased binding of CRY (data not shown).

To further elucidate the nature of the CRY/DNA interaction, we tested CRY’s ability to bind to single-stranded DNA and single- and double-stranded RNA. Our rationale for these additional experiments came from several observations. First, AtCRY3 is capable of binding to single-stranded DNA as efficiently as to double-stranded DNA (39). Second, RNA fragments were found to interact with *Vibrio cholerae* Cry1, another DASH-type member, when it was expressed and purified from *E. coli* (71). Third, the C terminus of *Neurospora* CRY contains multiple arginine-glycine-glycine (RGG) repeats, which usually participate in protein-RNA or protein-protein interactions (29). We found that *Neurospora* CRY was capable of binding double-stranded RNA (lane 7), single-stranded DNA (lane 11), single-stranded RNA (lane 13), and even an RNA-DNA hybrid molecule (lane 9). To begin to determine the relative affinity that CRY has for each type of nucleic acid, we performed a series of binding reactions using increasing amounts of CRY with a fixed amount of each nucleic acid species (dsDNA, ssDNA, dsRNA, or ssRNA) (Fig. 6C). CRY appears to exhibit similar affinities for dsDNA and dsRNA and a lower affinity for ssDNA. The low intensity of the ssRNA probe (bound or unbound) makes it difficult to quantitatively compare binding relative to that of the other three probes. Notably, multiple slower-migrating bands were seen in the binding reactions with dsDNA and dsRNA (Fig. 6C). The slower-migrating bands become more predominant as the CRY concentration increases, presumably due to multiple CRYs bound to each probe, supporting the notion that *Neurospora* CRY binds to dsDNA/dsRNA in a sequence-independent manner.

*Neurospora* CRY appears not to affect major regulation of either early or late light responses. Given that *Neurospora* CRY is a putative photoreceptor capable of interacting with DNA directly, we hypothesized that *Neurospora* CRY might have some light-related functions regarding gene regulation epistatic to WCC and decided to test it using microarrays with some light-related functions regarding gene regulation. It has been suggested that the epistatic to WCC and decided to test it using microarrays with some light-related functions regarding gene regulation.
by RT-PCR analyses (data not shown). In separate experiments, quantitative RT-PCR analyses in a ras-1\textsuperscript{bl} Δcry strain failed to find statistically significant increases in light induction of frq, al-1, or con-6 expression (22a). Although small effects on the expression of al-1 or con-6 have been recently reported (53), we expect the differences in results are due to genetic background effects rather than major undiscovered influences of CRY, and indeed the reproducible lack of major effects seen in our microarray analyses, which might well not report the reproducible lack of major effects seen in ground effects rather than major undiscovered influences of CRY. DrCRY shows more substantive transcriptional regulatory activity under nonlaboratory conditions or at other developmental stages in the Neurospora life cycle.

Analysis of long-term light phenotypes in the mutant cry strain. Given that CRY protein levels remain elevated under constant light exposure (Fig. 3D and E), we tested if there is any detectable long-term light-dependent developmental phenotype in the absence of cry. Constant light would trigger the carotenoid biosynthesis pathway, which can be seen in the accumulation of orange pigmentation. However, no gross defects in light-induced carotenoid biosynthesis can be detected (data not shown). Another light-regulated process, the development of Neurospora’s sexual spores in the perithecial organ, is also regulated by light (17). Positive phototropism of the perithecial beaks (beak bending, a maternal effect) is induced by blue light, resulting in the sexual spores being ejected toward the direction of light (32). We tested for defects in perithecial phototropism by inoculating crossing plates with one of the three strains (ras-1\textsuperscript{bl}, 343-25, or ras-1\textsuperscript{bl} wc-1\textsuperscript{ER53}) as the female parent and fertilizing these crosses with a WT strain. The plates were placed in directional lighting and then scored for the direction of the perithecial necks relative to the direction of the light. The WT perithecial necks displayed random growth directions when grown in the dark, whereas 82% of the WT perithecial necks pointed toward the light, as shown in Fig. 7C. The wc-1 mutant displayed a random distribution of perithecial necks both in the dark and with directional lighting. In contrast, 343-25 exhibited WT perithecial phototropism, with 74% of perithecial necks pointing toward the light. Having found no differences in 343-25 in the developmental processes known to be regulated by light nor in general growth rate (data not shown), we looked for novel phototropism during Neurospora’s asexual life stage. Different assays for phototropism were tested using a variety of culturing methods in combination with various directional lighting configurations (24). Culturing systems included standard shaking and static liquid cultures, solid media in petri plates, and race tube assays, including modified race tubes which enabled inoculation in the middle of the tubes to allow analysis of fluence responses. In order to study the fine branching structure of mycelia, we used thin vertical gels consisting of standard media poured between two glass plates similar to those used to electrophorese protein samples. These various culturing setups were combined with lighting configurations consisting of standard fluorescent lighting, sunlight, and custom-fabricated light-emitting diode arrays (blue, red, and white). The light sources and intensities were tested in a variety of configurations (e.g., high-intensity blue light above the vertical gels and low-intensity red light below). Under none of the conditions tested did we find any signs of phototropism in the WT or mutant cry strains (data not shown).

DISCUSSION

DASH-type CRY members have been identified from various organisms, ranging from bacteria and plants to fungi and animals. In Synchocystis sp. PCC 6803, CRY-DASH has been shown to have no photolyase activity in vitro but weak photolyase activity in vivo (36). The same protein has nonspecific DNA binding ability and possibly acts as a transcriptional repressor for a few genes (5). In Vibrio cholerae, two DASH-type members (Vcry1 and Vcry2) have no photolyase activity in vivo or in vitro (71). In Arabidopsis thaliana, the only DASH-type member, Atcry3, is capable of binding to single- and double-stranded DNA (nonspecifically) in vitro but without any conventional photolyase activity in vivo (39); however, biochemical and structural studies suggest that Atcry3 in vitro can act as a CPD photolyase with specificity for either single-stranded (37, 59) or looped double-stranded (55) DNA. Among animals, DASH-type members have been identified only in Xenopus laevis and Danio rerio (15); both have a weak photolyase activity when expressed in E. coli. No nonspecific DNA binding activity could be detected in vitro, and only DrCRY-DASH displays CPD binding activity on double-stranded DNA (15). Overall, although weak photolyase activity and DNA binding ability have been demonstrated for several DASH-type members, the definitive biological function of these DASH-type cryptochromes is still unclear: no strong phenotype could be observed in any case, and they might be involved in other biological processes not necessarily requiring DNA repair functions (5, 69). Because of this, we have focused on exploring clock and light phenotypes in the knockout strain of Neurospora crassa CRY, focusing on characteristics that have not yet been extensively examined in other DASH-type members. To be clear, the CryA recently reported in Aspergillus nidulans is actually a class I CPD photolyase based on both enzymatic and phylogenetic analyses (2).

Since it was first identified in 2003 (25), Neurospora CRY has been referred to as a cryptochrome ortholog based on sequence similarity. Later, it was categorized as a DASH-type member (5, 15), which is the only type of cryptochrome existing in the fungal kingdom; no animal or plant-type cryptochromes have been detected in the sequenced fungal genomes. However, it was surprising to us that free-running rhythms and a catalog of other light-regulated phenotypes are not perturbed in the absence of cry. Only entrainment in light cycles gave a mutant phenotype. The data clearly suggest that Neurospora CRY does not participate in the transcription-translation feedback loop as does its counterpart in other organisms, but this is in fact consistent with findings for other DASH-type members. For instance, in a transient transfection assay using an E-box-driven luciferase that is responsive to CLOCK:BMAL1, the DASH-type members in Xenopus laevis and Danio rerio effect no inhibition on the luciferase activity. In contrast, in the same assay, animal-type CRYs from the same organism (DrCRY1a) inhibit the luciferase activity completely (15), suggesting that DASH-type and animal-type CRYs are
functionally distinct from each other. Surprisingly, although *Neurospora* CRY is not a clock component and is dispensable for most light responses and various light-regulated developmental processes, the *cry* transcript is controlled by the circadian clock with peaks antiphasic to *frq*. Interestingly, the gene expression of another DASH-type member from tomato (*Solanum lycopersicum*) has been shown to be under the control of the circadian clock as well (22). The physiological significance of the circadian regulation of DASH-type CRYS, however, remains unclear.

Here, we showed that the transcript and protein levels of *Neurospora* CRY are both strongly and rapidly induced by light in a *wC-1*-dependent manner. However, whole-genome microarray analyses of mycelium samples collected under different light conditions indicate that there is no significant difference between WT and *cry* knockout strains at the transcriptional level. Given this, perhaps the major biological function of *Neurospora* CRY might be related to posttranslational regulation (54), or perhaps it becomes evident only at specific developmental stages or under particular growth conditions. For instance, in *Neurospora* the regulatory function of the opsin photoreceptor gene *nop-1* could be observed only in late developmental stages (4), and a recent report suggests that CRY can modulate the primary response elicited by WC-1 and WC-2 (53); this would perhaps provide an explanation for the small effects we report on the entrained phase of the conidia-conidiospore cycle in strains lacking CRY. That report (53) also provides confirmation of the light induction of CRY expressed in *Neurospora*. Knockout strains of *Ss cry1* exhibit a slight decrease in scerotal mass and increased numbers of pigmented hyphal projections on apothecial stipes under UV-A treatment but are otherwise developmentally normal. The study concludes that *Ss cry1* may have a function during UV exposure but is not essential for the developmental life cycle under laboratory conditions. Therefore, these principles may hold true for revealing additional biological functions of *Neurospora* CRY and other DASH-type members in the future.

Similar to most DASH-type cryptochromes, *Neurospora* CRY has no detectable photolyase activity in *vivo* and appears to bind FAD and MTHF when expressed in *E. coli*. In addition to its nonspecific DNA binding activity, which has been shown for other DASH-type members, we discovered that *Neurospora* CRY also has the capability to bind to single- and double-stranded RNA, as well as to a DNA-RNA hybrid. Although these properties might be shared among DASH-type family members, we speculate that this feature might be unique to *Neurospora* CRY due to the existence of multiple arginine-glycine-glycine (RGG) repeats at the C terminus, which are missing for all other DASH-type cryptochromes, including the *cry1* found in *S. cerevisiae*. RGG repeats are commonly found in proteins involved in regulation and coupling of RNA maturation events (29). RGG repeats are generally found at the C terminus of the protein and contribute to RNA binding nonspecifically (6, 28, 38, 52), both features of *Neurospora* CRY. Given the expression of *cry* RNA and protein late in the circadian cycle relative to most clock-regulated transcription, CRY may act via regulation of RNAs to fine-tune the phase of entrainment. Conversely, it may be worth reevaluating whether the capability of binding to both DNA and RNA is restricted to *Neurospora* CRY or widespread among other CRY-DASH members and if this function is tied to clock phenotypes in these other model organisms.
