Summary

Spectroscopic Probes

In order to investigate the properties of a material one must use an experimental probe, which will interact with the material. It is by examining the effect of this interaction that one is able to deduce or calculate a physical property of the material. There are two types of probe commonly used to investigate a material, transport and spectroscopic. A transport probe such as resistivity gives information about the density of electrons and the average time between electronic collisions as a function of temperature. A spectroscopic probe excites the material, and by varying the temperature one can investigate the superconducting and the normal state. Each different type of spectroscopic probe, probes a different aspect of the material, so that all of them together provide a complete picture. Some examples of spectroscopic probes are FIR (Far Infrared), Raman, Angle Resolved Photo Electron Spectroscopy (ARPES), Inelastic Neutron Scattering (INS), Muon Spin Resonance ($\mu$SR) and Nuclear Magnetic Resonance (NMR). A spectroscopic probe can produce an electronic excitation, a collective excitation or a nuclear excitation. One can either measure the incoming and outcoming beam or the excitation produced. In Nuclear Magnetic Resonance (NMR) one excites the oxygen and copper nuclei, which before relaxing interact with the valence electrons. Inelastic Neutron Scattering (INS) provides information about the magnetic excitations such as magnons. In Inelastic Neutron Scattering a beam of monochromatic neutrons impinges upon the material and one measures the scattered beam. Having measured the energy and momentum ($E,k$) of the incoming and outcoming neutrons one can calculate the dispersion relationship for the excitations. These may be phonons or magnons. In Photo Electron Spectroscopy (PES) the material is excited by a beam of photons but one measures the outcoming excited electrons. Here the exciting particle (photons) are not the same as the measured particle (electrons). Very often a model will be used to predict the outcome of an experiment. By comparing theory with experiment a better understanding of the material is obtained.

In Far Infrared Spectroscopy (FIR) we excite the material with photons (electromagnetic waves) of different energy and measure the rate of absorption. In this thesis we use reflectivity as a measure of the absorption. In order to obtain the absolute reflectivity, a perfectly reflecting mirror is used as a reference. Wherever the absolute reflectivity deviates from one, the material has absorbed...
or transmitted photons at this frequency. The conservation of energy holds so that \( R + T + A = 1 \), where \( R \) is the absolute reflectivity, \( T \) is the transmissivity and \( A \) is the absorption.

The normal approach to determining whether a material is a metal, insulator or a semiconductor is to examine the frequency dependence of the reflectivity. A metal has a high reflectivity up to the plasma frequency, a semiconductor has a small and an insulator has a large energy gap with clear phonons.

For simplicity one often uses the independent particle approximation for the theoretical description of solids, even though electrons interact both directly (via Coulomb interaction) and indirectly (via electron-phonon interaction) with each other. This approach breaks down when the interaction energy of the particles is larger than the kinetic energy. This situation occurs in strongly correlated electron systems (SCES) and the HTSC's are considered to fall into this category.

Single electron band calculations predict the parent compound \( \text{La}_2\text{CuO}_4 \) to be a metal whereas it is an insulator. Not only are the HTSC's strongly correlated, but also anisotropic which means their optical and transport properties depend upon which optical axis is being excited or along which axis the transport takes place. The cuprates are therefore complex materials for which the current solid state theory is inadequate.

Far infrared spectroscopy is the probe used in this thesis to investigate the HTSC's. The measurements were performed over a temperature range of 4K to 300K in a 113v Bruker Fourier Transform Infrared (FTIR) spectrometer. This spectrometer allows the material to be probed over a range of frequencies in one or two seconds. Repeating this measurement improves the noise statistics of the spectrum. For weak signals or small samples several hundred scans are normally performed. FIR spectroscopy measures the dressed electronic excitations (usually called quasiparticles), both in-phase (real part of \( \sigma \)) and out of phase (imaginary part of \( \sigma \)) values of the conductivity are obtained. The energy range of the spectrometer was 10 - 8000 cm\(^{-1}\). The superconducting energy gap for all HTSC's falls within this range. If one uses the BCS weak coupling relationship \( 2\Delta/kT_c=3.5 \), then for \( \text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4 \) ( \( T_c \approx 32K \)) the gap energy \( 2\Delta \approx 82 \text{ cm}^{-1} \) (10 meV). For \( \text{HgBaCaO} \) ( \( T_c \approx 132K \)) the gap is \( \approx 340 \text{ cm}^{-1} \) (41 meV). Even if we assume the case of extremely strong coupling e.g. \( 2\Delta/kT_c=7 \), then the superconducting gap still falls within the measurement range of the spectrometer.

**Symmetry of the Order Parameter**

Near normal incidence, when the angle of incidence \( \theta \) of the incoming beam is \( \approx 5^\circ - 7^\circ \), FIR spectroscopy has a limitation when measuring the spectrum of materials which are highly reflecting i.e. \( R \approx 1 \). The resulting optical conductivity then depends upon the noise level in the reflectivity measurements. Certainly if small changes on a low level they will be reflected in the reflectivity is on then the analysis of such a measurement incidence \( \theta \) is now by \( 1/\cos \theta \). If \( \theta \) is small the analysis approaches PARIS (Polarized Angle Resonant Incidence Spectroscopy). This novel technique allows the determination of the shape of \( \sigma \) in the presence of the optical properties of the material. The shape of \( \sigma \) depends upon the symmetry of the order parameter. By measuring the conductivity measurements of \( \text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4 \) at 29K show that no clear anisotropy is observed. This implies that the order parameter, one can deduce the symmetry of the order parameter.

High accuracy measurements of the order parameter imply that the overdoping of the HTSC's is more like a three-dimensional metallic system for which the collective properties of the Cooper pairs are expected to dominate. In this case the over doping is expected to result in a higher conductivity at lower temperatures. Below \( T_c \), a collective excitation is observed, and it's frequency is below the normal dispersion limit. For \( \text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4 \) this is expected to be around 100 cm\(^{-1} \) (10 meV) and for \( \text{HgBaCaO} \) around 200 cm\(^{-1} \) (20 meV).

**The \( c \) Axis Electro-optic Effect**

The HTSC's are characterized by a strong \( c \)-axis optical anisotropy. Near normal incidence the \( c \)-axis optic is observed to have a large increase in the Mott-Ioffe limit of the \( c \)-axis conductivity. This is due to the collective excitation of the Cooper pairs, and it's frequency doubles i.e. the superconducting gap energy
Single Layer HTSC's

A simple picture of energy holds so the transmission and reflection coefficients of a metal, insulator or semiconductor have a metal, insulator or semiconductor, where the reflectivity is one. A semiconductor has a gap between energy levels, and a metal has a gapless Fermi sea. The reflectivity is a measure of the absorption and the sensitivity will be increased by 1 / sin θ. If θ is increased to 80°, the sensitivity is increased by a factor of 6. Therefore small superconductivity induced changes are amplified by a factor of 6. This novel technique is the basis of this thesis and is referred to by the acronym PARIS (Polarized Angle Resolved Infrared Spectroscopy).

The shape of σ(ω) contains information about the symmetry of the order parameter. By modelling the conductivity based upon a s and a d-wave order parameter, one can compare the calculations with measurements and comment upon the symmetry of the order parameter for that particular material. PARIS measurements of La$_{1.65}$Sr$_{0.15}$CuO$_4$ (T$_c$ = 32K) and for La$_{1.66}$Sr$_{0.24}$CuO$_4$ (T$_c$ = 29K) show that no clear gap develops in the conductivity spectrum at 4K. This implies that the order parameter cannot be s-wave. Model calculations using a d-wave order parameter show a reasonable agreement. This does not affect the validity of the Ginzburg-Landau theory. It had long been assumed that the effective number of charge carriers continued to increase in going from the optimally doped case to the overdoped situation. But it was never understood why T$_c$ decreased. High accuracy measurements of La$_{1.80}$Sr$_{0.20}$CuO$_4$ show in fact that the effective number of charge carriers decreases and so tracks T$_c$ (see chapter 3).

The c Axis Electrodynamics

The HTSC's are characterized by a metallic ab-plane conductivity and a insulator-like c-axis conductivity. Within a simple picture they may be viewed as two dimensional metallic sheets separated by insulating material. Near normal incidence FIR measurements of La$_{1.65}$Sr$_{0.15}$CuO$_4$ (optimally doped crystal) shows that the conductivity in the normal state is 8 (Ω cm)$^{-1}$ at 40K which is below the Mott-Ioffe limit of 100 (Ω cm)$^{-1}$ for a metal. There is no zero crossing of ε$_1$, which normally denotes the plasma frequency. Furthermore the scattering rate exceeds the theoretically calculated plasma frequency which is a very unusual situation. Below T$_c$, a plasma edge appears at 50 cm$^{-1}$. This is unusual in that its frequency is below the BCS gap value of 82 cm$^{-1}$, therefore it is a sub-gap collective excitation. Measurements on the overdoped crystal La$_{1.80}$Sr$_{0.20}$CuO$_4$ show a large increase in the conductivity σ$_1$ at 40K but the value is still below the Mott-Ioffe limit of 100 (Ω cm)$^{-1}$. As the c-axis conductivity becomes more metallic, T$_c$ decreases. For a change of 3K in the critical temperature, the plasma frequency doubles i.e. it becomes 100 cm$^{-1}$ which is unexpected (see chapter 4).
Experimental Test of the Anderson Interlayer Tunnelling Model

P. W. Anderson and coworkers proposed that the frequency of the c-axis plasma edge was the Josephson plasma frequency $\omega_J$. Furthermore that the critical temperature $T_c$ was directly proportional to $\omega_J$. This was a consequence of the Inter Layer Tunnelling (ILT) model. Due to the complicated coupling structure in a material with more than one copper-oxygen plane per unit cell, this model was applicable only to single layer compounds. The Josephson plasma frequency can be calculated, as it is based upon physical parameters. The calculated and measured value of $\omega_J$ for La$_{1.85}$Sr$_{0.15}$CuO$_4$ are in reasonable agreement with each other. The question remained as to whether it was valid for other single layer compounds. The concept had not been tested due to the lack of availability of crystals with sufficient c-axis dimensions to perform optical measurements. Crystals of Tl$_2$Ba$_2$CuO$_6$, Nd$_{1.85}$Ce$_{0.15}$CuO$_4$ and Bi$_2$Sr$_2$CuO$_6$ were available but only with c-axis dimensions of 50 - 100$\mu$m. However as the plasma edge is a longitudinal excitation it may be detected using the PARIS technique. The assumption was tested and verified on a crystal of La$_{1.85}$Sr$_{0.15}$CuO$_4$ where the plasma edge was correctly detected. Reflectivity measurements on Tl$_2$Ba$_2$CuO$_6$, Nd$_{1.85}$Ce$_{0.15}$CuO$_4$ and Bi$_2$Sr$_2$CuO$_6$ did not show a plasma edge near the predicted value. In fact no plasma edge was measured within the measurement range. The ILT model prediction for $\omega_J$ appears to be incorrect (see chapter 5).
