Ageing is accompanied by decreased overall fitness and performance. Studying brain ageing in humans is challenging due to limited or no access to healthy tissue, limited opportunities for interventions and complicated confounding factors. The generation of mouse ageing models with uniform genetic backgrounds significantly contributed to understanding (brain) ageing at the molecular level. Research has focused on evolutionarily conserved mechanisms or pathways that control ageing to facilitate data extrapolation to humans. Understanding how these pathways contribute to pathological ageing may help us understand human central nervous system (CNS) ageing and assist in the development of possible therapeutic targets. In this review, we focus on the functional consequences and pathological changes in the CNS of ageing mouse models.

Introduction

Ageing is the main risk factor for many neurodegenerative diseases. Understanding how normal brain ageing transitions to pathological ageing is of vital importance to develop possible treatment for ageing associated central nervous system (CNS) pathologies.

To investigate CNS ageing, a range of ageing mouse models was developed, in view of the genetic similarity between mice and humans, their relatively short life span and amenability for genetic manipulation [1]. Human and mouse brain ageing exhibit many common features. On the pathological level, brain atrophy, neuronal loss, neuronal lipofuscinosis and reactive glial cells are observed following ageing in both human and mouse brain [2]. On a functional level, both humans and mice show an age-dependent decline in learning and memory and motor performance [3]. On a transcriptional level, common sets of genes are affected by ageing in mouse and human [4]. On an epigenetic level, DNA methylation is strongly correlated with ageing [5], and age-associated DNA methylation changes are relatively well conserved between humans and mice [6].

However, it is worth noting that there is very limited correlation between age regulated gene expression changes in mouse and human, indicating that the ageing process in the CNS of human and mice might be quite different [7,8]. Given that age regulation is quite different in different tissues and species [7], research has focused on evolutionarily conserved mechanisms that control ageing to facilitate data extrapolation to humans. These conserved pathways or mechanisms include genomic instability, epigenetic alterations, telomere attrition, mitochondrial dysfunction, loss of proteostasis and nutrient sensing pathways etc. [9,10].
In this review, mouse models that have been used to study CNS ageing and ageing-related diseases will be discussed with the main focus on pathological changes during CNS ageing.

**Mouse models with genomic instability**

Brain ageing is characterized by loss of genomic integrity [11]. Excessive DNA damage and insufficient DNA repair both can contribute to genomic instability during the ageing process [12]. Numerous mouse models with genomic instability have been established and extensively reviewed [13,14]. Here, we only focus on models with CNS ageing phenotypes. Detailed CNS phenotypes of these mice are described in Table 1.

**Mouse models with excessive DNA damage**

**Atm-deficient mice**

Ataxia-telangiectasia (AT) is a human genetic disorder caused by mutational inactivation of the ATM gene [15]. ATM plays a major role in maintaining genomic stability and DNA strand breaks accumulate in the brain of Atm−/− mice [16]. ATM dysfunction resulted in increased reactive oxygen species (ROS) production, which may induce the degeneration of cerebellar neurons [17]. The histological, immunohistochemical and electrophysiological properties of Purkinje cells (PCs) were not altered in cerebellum, however, these cells showed age-dependent defects in calcium spike bursts and calcium currents [18]. Atm deficiency induced progressive loss of dopaminergic neurons in the substantia nigra (SN) and GABAergic neurons in the striatum (STR) [19]. Atm deficiency was also shown to impair astrocyte-endothelial cell interactions, which could be the underlying mechanism for neurodegeneration [20].

**BubR1 deficient mice**

BubR1 is a mitotic checkpoint protein that is essential for the accurate separation of duplicated chromosomes during cell division. Reduced BubR1 expression induces aneuploidy, which affects genomic stability [21]. BubR1 insufficient mice (BubR11/1H mice) exhibited various motor deficits, including impaired motor strength, coordination, gait patterns and reduced locomotor activity. BubR1 expression is significantly reduced with natural ageing in the mouse brain, and BubR11/1H mice exhibit age-related decline in hippocampal neurogenesis [22]. The oligodendrocyte progenitor cell proliferation and oligodendrocyte density were markedly reduced in brain and spinal cord, which further caused axonal hypomyelination [23]. Besides, BubR11/0H mice also showed cerebral degeneration and accelerated gliosis in the brain [24].

**DNA methyltransferase deficient mice**

DNA methyltransferase 1 (Dnmt1) is the most prevalent DNA methyltransferase that maintains genomic methylation stability. Dnmt1 haploinsufficiency impaired learning and memory function in an age-dependent manner in mice [25]. In addition, conditional deletion of Dnmt1 and Dnmt3a in neurons induced abnormal long-term plasticity in CA1 and deficits of learning and memory; however, no neuronal loss was observed [26].

**DNA damage repair deficient mice**

DNA damage alters the structure of DNA and most DNA damages undergo repair. Excess DNA damage is associated with ageing and cancer. There are several DNA repair pathways for different types of DNA damage. Deficiencies in DNA repair pathways cause progeria syndromes in humans and also affect the CNS [27]. Several ageing mouse models were established based on deletion or mutation of genes involved in DNA repair pathways.

**Ercc1 deficient mice**

Excision repair cross-complementation group 1 (ERCC1) is an essential component of multiple DNA repair pathways: nucleotide excision repair (NER), double-strand break repair and interstrand cross-link repair pathways [28]. Mice carrying a knock out and a hypomorphic allele for Ercc1 showed age-dependent motor abnormalities and cognitive decline. Further studies revealed widespread astroglisisis, microgliosis and neuronal degeneration in the brain, and motor neuron loss in the spinal cord [28,29]. The mutant mice did not show altered synapse numbers and dendritic morphology in the hippocampus. However, Ercc1L−/− mice did show age-dependent changes in the proteomic composition and synaptic plasticity in the hippocampus [30]. A similar age-related cognitive decline and neurodegeneration were also observed in conditional knockout mice (ErccL2H/Mice, in which Ercc1 deficiency was directed to excitatory forebrain neurons [28]. For microglia, we have shown that microglia in Ercc1L−/− mice exhibit a hypertrophic morphology with thickened primary processes and larger cell bodies at the age of 16 weeks. Functionally, Ercc1L−/− microglia displayed increased phagocytosis, proliferation and ROS production. Ercc1L−/− microglia displayed an exaggerated proinflammatory response to a systemic inflammatory lipopolysaccharide (LPS) challenge, indicative of a “primed” state. Transcriptome analysis also confirmed Ercc1L−/− microglia were primed, with a clear phagocytic and chemotactic profile and enhanced immune state [31,32].

**Xpg mice**

The premature ageing syndrome Cockayne syndrome (CS) is characterized by growth failure, abnormal sensitivity to light and impaired development of the CNS [33]. In humans with CS, the DNA repair gene XPG that is involved in NER, homologous recombination repair and base excision repair (BER) is mutated. XPG−/− mice exhibit multiple progressive features of CNS ageing, such as loss of hearing and vision, cognitive decline, motor deficits and early development of tremors [34]. Xpg−/− mice develop widespread astroglisis...

and microgliosis in brain and spinal cord, starting at 4 weeks of age. At 14 weeks of age, astrogliosis was severe and associated with axonal swellings and loss of PCs in the cerebellum. The genotoxic stress marker p53 was detected in neurons, astrocytes and oligodendrocytes. Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) showed a significant increase in apoptotic cells in the cerebrum at 4 as well as 14 weeks of age [35].

Csα and Csβ / mice

Csα and Csβ are genes involved in transcription-coupled excision repair (TCR) In Csα/− and Csβ/− mice, activated microglia and astrocytes are detected in the white matter. However, microglia activation was not observed in NER-deficient Xpa/− and Xpc/− mice. Therefore, next, TCR-deficient mice were generated with selective NER deficiency targeted to forebrain neurons. Csβ/−/Xpa[−/−]CamKIIα-Cre mice displayed dramatic age-related neuronal loss, behavioral abnormalities, and brain atrophy in the forebrain [36].

Sirt6 deficient mice

Sirtuins (SIRT1–SIRT7) are an evolutionally conserved family of NAD+-dependent deacetylases, and play a critical role in brain ageing and neurodegenerative diseases [37]. SIRT6 promotes DNA repair and its activity declines with age. Sirt6 overexpression expanded life span in male mice [38]. Sirt6 knockout mice exhibit an accelerated ageing phenotype and die prematurely. Sirt6 specific depletion in the brain results in increased DNA damage, Tau phosphorylation and learning defects [39].

3xTg/Polβ/−/ mice

DNA polymerase beta (Polβ) is a primary polymerase involved in BER. Disruption of Polβ induced growth retardation and post-natal lethality in mice. A 50% reduction in Polβ levels (heterozygous for Polβ gene) aggravated the phenotypes of 3xTg Alzheimer’s Disease (AD) mice. Neuronal dysfunction, cell death and memory impairment were also shown to be more severe than in the 3xTg AD mice or Polβ+/− mice. Pathway comparison analysis of human and mouse microarray data revealed that the combined 3xTg/Polβ+/− transgenic mouse is more similar to human AD patients than the 3xTgAD or Polβ+/− mice [40].

Telomere attrition mouse model

Telomere shortening is observed in all eukaryotes [41]. Mice carrying a homozygous germ line deletion for the telomerase RNA component gene (Terc) showed complete loss of Terc expression and telomerase activity. For the Terc/−/− mice, the telomerases become shorter during successive generations of mating due to the replication end-point problem, usually resulting in phenotypic changes after the third generation. Third generation Terc/−/− mice showed impaired spatial learning memory, and accordingly, the dentate gyrus (DG) volume and brain weight were decreased in the Terc/−/− mice [42]. Further study revealed reduced neurogenesis in the DG and loss of neurons in the hippocampus and frontal cortex in third generation Terc/−/− mice [43]. Telomere dysfunction also led to reduced microglial numbers and cell body volume in DG, nevertheless, telomere shortening did not affect microglial proliferation or induce an ageing phenotype [42,43]. Terc/−/− microglia also exhibited an enhanced pro-inflammatory response to peripheral LPS stimulation. However, unlike Ercc1−/− microglia, this enhanced response is correlated with brain infiltration and blood–brain barrier dysregulation rather than age-related microglia priming [44]. Terc deficiency was also studied in combination with several age-related disease mouse models. Telomere shortening was shown to accelerate the amyotrophic lateral sclerosis (ALS) phenotypes in SOD1G93A transgenic mice and Parkinson’s disease (PD) phenotypes in (Thy-1)-h[A30P] α-synuclein transgenic mice [45,46]. Surprisingly, telomere shortening reduced AD amyloid pathology in APP23 transgenic mice [43].

Telomerase reverse transcriptase (TERT) is the catalytic subunit of the telomerase complex. Its deficiency also induced ageing phenotypes quite similar to Terc/−/− mice [47]. What differed is that TERT deficiency induced aggressive and depressive behaviors in a mouse brain structure-specific manner [48]. Tert gene knockout mice also display impaired spatial memory, dendritic development and neuritogenesis [49]. Detailed CNS phenotypes of these mice are described in Table 1.

Mouse models with mitochondrial dysfunction

It is well accepted that mitochondria play a central role in ageing and neurodegenerative diseases [50]. Commonly used mouse models with mitochondrial dysfunction include dopaminergic neuron specific Twinkle transgenic mice, mitochondrial late-onset neurodegeneration (MILON) mice, mitochondrial quality control gene Afg3l2, Spg7, Phb2 and HtrA2/Omi-deficient mice, apoptosis-inducing factor Aif deficient mice and mito-Pst1 transgenic mice all showed substantial brain ageing and neurodegeneration phenotypes [51]. Detailed CNS phenotypes of these mice are described in Table 1. Due to premature death of HtrA2/Omi deficient mice, this mouse model is not discussed here [52].

Mouse models with deficits in proteostasis

Loss of proteostasis is observed in many neurodegenerative diseases such as AD and PD. In mammals, proteostasis is maintained by chaperones and two proteolytic systems, the ubiquitin-proteasome and the lysosome-autophagy systems [10]. Autophagy-deficient mice showed ageing related changes and neurodegenerative changes that resemble those associated with ageing [53], among them, Beclin1, Atg7 and FAK family-interacting protein of 200 kDa (FIP200) deficient mice showed neurodegeneration phenotypes (see Table 1).
Defects in the sphingomyelinases gene Smpd3 resulted in age-dependent neuronal dysproteostasis in Smpd3−/− mice, causing accumulation of APP, Aβ, and phosphorylated Tau (pTau) in neurons. The deficient mice also showed age-dependent decline of motor activity, coordination and cognitive ability [54]. Endoplasmic reticulum (ER) is important to maintain proteostasis, as approximately 30% of proteins are synthesized and processed there. ER stress is also a common pathological signature in a variety of diseases, including neurodegenerative disease [55]. Binding immunoglobulin protein (BiP) is central for ER function and mutant BiP mice exhibited motor disabilities during ageing. Degeneration of motoneurons and accumulations of ubiquitinated proteins were also found in the spinal cord [56].

**Mouse models with deficits in nutrient sensing**

The insulin/insulin-like growth factor 1 (Insulin/IGF1) signaling pathway is evolutionarily conserved and involved in growth, development, metabolic homeostasis and also CNS ageing [57]. IGF1 is a neuroprotective hormone that is mainly produced in the liver. Conditional, liver-specific inactivation of the Igf1 gene induced an age-associated decline in learning memory. Further study identified astrocytosis and increased neurochemical disturbances in the DG area [58]. Reduced hippocampal IGF-1 receptor (IGF1R) expression is associated with age-related decline in learning, and astrocyte-specific knockout of IGF1R was demonstrated to induce impairments in working memory [59]. Forkhead box O (FOXO) transcription factors play a pivotal role in the IIS/PI3K/Akt signaling pathway. They are important determinants of ageing and longevity [60]. FOXO expression progressively increases in ageing human and mouse brains [61]. Conditional knockout of Foxo 1, 3, and 4 in neurons and glia cells induced an accelerated ageing phenotype in mice, manifested by axonal tract degeneration and gliosis [61].

**Senescence accelerated mouse-prone (SAM-P) mice**

The SAM-P mice are naturally occurring mouse lines that display a series of accelerated ageing phenotypes. At present, there are eight strains of SAM-P. It is noteworthy that each SAM-P strain has relatively strain-specific pathological phenotypes [62]. Since SAM-P/8 and SAM-P/10 display deficits in learning and memory, these strains were extensively used to investigate CNS ageing. A variety of age-associated alterations involving neurons, glia and blood brain barriers have been identified in SAM-P/8 and SAM-P/10 mice brain. SAM-P/8 could also serve as an animal model for AD and other dementias as age-related increases in pTau and amyloid accumulation were also observed in the hippocampus of SAMP8 mouse brains [63]. The 3xTg-AD transgenes in a SAM-P/8 background showed deficits in spatial memory and female-specific aggravation of AD pathology characterized by activation of astrocytes and increased accumulation of pTau and amyloid in the brain [64]. Some epigenetic alternations associated with ageing and neurodegeneration were also identified in the SAMP-P/8 brain [65,66].

**Promising therapeutic targets**

Although ageing itself is an inevitable process, interventions could be applied to extend both lifespan and health-span. A longevity study in monozygotic twins indicated that life span is determined largely by environmental factors rather than genetic factors [67]. Work on mouse models of ageing has not only contributed to the identification of many of the molecular pathways involved in ageing, but also have provided possible targets for the treatment of age-related CNS decline. Epigenetic signatures are proposed to function as biomarkers of ageing, for example, the DNA methylome can help to measure human ageing rates [5]. Epigenetic modifications are considered to be dynamic and reversible, making it an attractive therapeutic target. Chromatin modifying compounds such as sirtuin modulators and histone deacetylase inhibitors are thought to provide a promising treatment for neurodegenerative diseases [68,69].

In recent years, senescent cells are recognized as a new target for age-related disease. In mouse, clearance of p16Ink4a-positive senescent cells was shown to delay ageing-associated phenotypes in BubR1H/H mice [70]. Fuhrmann-Stroissnigg et al. established a drug-screening platform to identify senolytic compounds using Ercc1−/− primary murine embryonic fibroblasts. Through this platform, they successfully identified an HSP90 inhibitor, 17-DMAG, which could extend health-span and delay the onset of several age-related symptoms in Ercc1−/− mice [71]. Microglia are shown to undergo age-dependent degeneration, increasingly displaying a primed or hyperreactive, pro-inflammatory phenotype and a deficiency in phagocytosis and chemotaxis. Senescent microglia are believed to be involved in switching normal brain ageing to pathological ageing [72]. The rejuvenation of senescent microglia was already shown to be a potential druggable target [73]. However, so far, there is no evidence whether microglia senolysis could restore normal function and revert or halt CNS ageing phenotypes.

Dietary restriction increases lifespan or health-span in all investigated eukaryote species [10]. A similar effect is seen when the activity of nutrient-sensing pathways is reduced by mutations or chemical inhibitors [74], indicating that nutrient-sensing pathways could provide promising targets to slow ageing. For example, the Insulin- and IGF-1-signaling pathway, the mammalian target of rapamycin (mTOR) pathway and the AMPK pathway are involved in nutrient sensing. And, manipulation of these pathways could increase lifespan and delay multiple aspects of ageing [10,75,76].

**Conclusions**

Studying brain ageing in humans is challenging due to very limited or no access to healthy tissue, limited opportunities
for interventions and human ageing in general is complicated by confounding factors like environment, nutrition, medical history, medication, education etc. The generation of mouse models with uniform genetic backgrounds significantly contributed to our understanding of ageing at the molecular level. However, conclusions must be drawn with caution because the results obtained from inbred mice may not represent the species as a whole [77]. Also, the mouse models cannot recapture all the brain ageing phenotypes in human, nor reliably predict age-related changes in humans owing to differences in the ageing process in human and mouse.

Though the mouse models described here have been used to identify molecular mechanisms of ageing, and to identify possible therapeutic targets, their use in the development of therapies and in particular the translation to the human situation is still not well developed [78]. In case of AD, for example, gene mutations that lead to AD-like phenotypes in young animals do not fully mimic human AD in older patients and therefore the predictive value of testing drugs in such models is limited [79].

Nonhuman primates are more similar to humans in how they experience ageing processes, which include ageing related pathologies like cancer, diabetes, arthritis, cardiovascular disease, and neurological decline. However, their substantial size, long lifespan, and the associated expense are prohibitive factors in their large scale-use for research into ageing. Nonetheless, they could provide a crucial component between the bench and the bedside [80]. In this review, we mainly focused on the functional consequences and pathological changes resulting from conserved pathways dysfunction in brain ageing. Understanding how these conserved pathways contribute to pathological ageing may help us to get a better understanding of brain ageing and develop possible treatment strategies. Finally, it is worth noting that the ageing process involves multiple organs and tissues, and the influence of peripheral organs on CNS ageing cannot be ignored.
