Supporting Information

ABSTRACT: Molecular rotary motors based on oxindole which can be driven by visible light are presented. This novel class of motors can be easily synthesized via a Knoevenagel condensation, and the choice of different upper halves allows for the facile tuning of their rotational speed. The four-step rotational cycle was explored using DFT calculations, and the expected photochemical and thermal isomerization behavior was confirmed by NMR, UV/vis, and CD spectroscopy. These oxindole motors offer attractive prospects for functional materials responsive to light.

INTRODUCTION

The emergence of artificial molecular machines has allowed the chemist to control motion at the nanoscale. Among these machines, molecular rotary motors are particularly attractive, owing to their unique ability to undergo repetitive unidirectional rotation and to drive systems out of equilibrium. Overcrowded alkene-based motors, which are driven by light, have shown great potential in a number of fields, such as soft materials, catalysis, and surface chemistry, enabling responsive and dynamic behavior. They were first reported by our group in 1999 and since then, second and third generation molecular motors have been developed and their functioning has been thoroughly investigated. Through synthetic modification, the rotational speed can be tuned, and recently, alternative methods to dynamically control their rotation have been developed. A major challenge that remains, for molecular motors to reach their full potential, is to drive the rotation with visible light instead of harmful UV light. Strategies to shift the excitation wavelength to the visible range have been developed, for example, by making use of photosensitizers, extended π systems, or push–pull substituents. Apart from adapting the design of existing motors, new types of light-driven molecular motors are highly warranted. Loh and co-workers reported easily accessible molecular motors based on imines, and the group of Dube developed molecular motors based on hemithioindigo. Here we present molecular motors that are based on arylidene oxindoles, which are easily accessible by a condensation reaction and can be operated by visible light.

The group of Lušák showed that some arylidene oxindoles undergo E–Z isomerization when exposed to sunlight, but the potential of these compounds as photoswitches has, to the best of our knowledge, not yet been explored. Inspired by the facile synthesis and the interesting spectroscopic properties of arylidene oxindoles, we envisioned a new design for a molecular rotary motor.

Our design features an N-methyloxindole lower half and an upper half similar to molecular motors based on overcrowded alkenes connected through a central double bond functioning as a rotary axle (Scheme 1a). Molecular motors 1–4 can be readily synthesized, and the oxindole scaffold provides an attractive handle for further functionalization. For distinct application, often a specific rotational speed is required. Therefore, structures with five- and six-membered rings (X = CH₂, O, and S) were chosen, in analogy to other molecular motors based on overcrowded alkenes, as they have shown to have large differences in rotational speed. These upper halves all bear a methyl stereocenter that dictates the direction of rotation. A rotation cycle much like molecular motors based on overcrowded alkenes is proposed, with the first step being a photochemical E–Z isomerization (PEZ) converting stable E-1 to unstable Z-1 (Scheme 1b). In this isomer, the methyl at the stereocenter adopts an unfavorable (pseudo)axial orientation. To release some of the strain, both halves can slip along each other in a thermal helix inversion (THI), forming stable Z-1 and completing the first half of the rotary cycle. In a similar fashion, a second photochemical isomerization followed by a THI takes place to complete a 360° rotation. Key to the unidirectional rotation is that upon photochemical E–Z isomerization, an unstable state is formed that undergoes an energetically downhill THI process, in a forward direction being more favorable than a backward Z–E isomerization.

RESULTS AND DISCUSSION

Initially, DFT calculations were performed to predict the structural parameters and the relative energies of the different isomers of oxindole-based motors 1–4 (Figure 1). All structures were optimized using the B3LYP functional with a 6-31+G(d,p) basis set. Additionally, a IEFPCM, DMSO solvation model was chosen as previous studies with arylidene oxindoles were carried out in DMSO. The calculated relative Gibbs free energies of all stable and unstable states as well as the transition states (TS) for THI are shown in Figure 1. In all cases, two unstable states are found that are much higher in energy than their respective stable states with opposite helicity. This energy difference is crucial to ensure unidirectionality in the rotary cycle of molecular motors. The relative energy barriers for THI of all motors are summarized in Table 1.

*DiHedral angle 1–2–3–4 in unstable-Z as shown in Scheme 1b.

Oxindole motors 1–4 were synthesized in a single step by a Knoevenagel condensation of commercially available N-methyloxindole and the corresponding ketone, mediated by a combination of TiCl\(_4\) and DBU (Scheme 2). The ketones were
synthesized in one to four steps following well-established literature procedures, thus making these molecular motors very easily accessible. In all cases the E-isomer was exclusively obtained. According to DFT calculations, this isomer is the most stable one (vide infra).

With these four different motors in hand, the photochemical and thermal isomerization behavior was first monitored by $^1$H NMR spectroscopy with $\lambda_{\text{max}} = 365$ nm light. Upon irradiation of an NMR sample of E-1 in DMSO-$d_6$ at room temperature, a new set of signals appeared indicative of unstable Z-1 (PSS$_{365}$ = 76:24). Upon heating to 100 °C, the unstable isomer was converted to the original isomer (stable E-1), and as a consequence, a 360° rotation was successfully achieved. The cycle was repeated using $\lambda_{\text{max}} = 420$ nm light (Figure S3), showing that rotary motion can also be achieved with visible light.

A similar rotational cycle was observed for motor 2 in THF-$d_8$ (Figure S5). THF was chosen as low temperature studies were needed. Irradiation of a sample of 2 with $\lambda_{\text{max}} = 365$ nm light at −25 °C revealed the emergence of unstable Z-2 (PSS$_{365}$ = 77:23), which underwent THI to stable Z-2 when the sample was allowed to warm to room temperature. Subsequent irradiation afforded unstable E-2 (PSS$_{365}$ > 99:1), which converted to the original isomer (stable E-2) when the sample was heated to 55 °C. Similar results were obtained when the rotary cycle was performed using $\lambda_{\text{max}} = 455$ nm light (Figure S6).

For motor 3, for which the highest barriers for THI were calculated (vide infra), the first part of the cycle was found to be identical to that of motors 1 and 2 (Figure S7). Irradiation of an NMR sample of 3 in DMSO-$d_6$ with $\lambda_{\text{max}} = 365$ nm light at room temperature (PSS$_{365}$ = 79:21) and subsequent heating to 100 °C showed the formation of stable Z-3. The sample was again irradiated to show the appearance of unstable E-3 (PSS$_{365}$ = 95:5); however, when it was heated, degradation was observed. Most likely, degradation is due to the high temperature required to trigger THI, owing to the high isomerization barrier for this compound ($\Delta^G^\text{calc}$ = 120.2 kJ mol$^{-1}$).

Due to the low barrier for THI, unstable Z-4 could only be observed when irradiated at −90 °C (Figure S8), which was performed in CD$_2$Cl$_2$. Even at this low temperature, unstable Z-4 was observed to already undergo slow THI to form stable

Z-4. At the same time, this isomer then undergoes a photochemical E–Z isomerization, forming unstable E-4 over time. When warming this sample to −45 °C, stable E-4 is again reformed, completing 360° rotation.

Next, the photochemical and thermal isomerization behavior of motors 1–4 was studied using UV/vis spectroscopy. They all show a broad absorption band with \( \lambda_{\text{max}} \) between 350 and 400 nm, which extends into the visible region (Figure 3). Very little solvatochromism (≤5 nm) was observed over a range of different solvents, including aromatic and protic solvents (Figure S12). The rotational cycle of motor 1 was additionally studied using CD spectroscopy. Its enantiomers were separated using chiral supercritical fluid chromatography and could be identified by comparing their CD spectrum to the DFT calculated spectrum (Figure S10). When a UV/vis sample of stable E-(S)-1 in DMSO was irradiated with \( \lambda_{\text{max}} = 365 \) nm light, a bathochromic shift in both the UV and CD spectra could be observed, signifying the formation of unstable Z-(S)-1 (Figure 3). Interestingly, isomerization could also be achieved with visible light of wavelengths up to 455 nm, albeit with a lower PSS, which is most likely due to the stronger absorption of the unstable isomer at longer wavelengths. Heating the sample to 60 °C leads to a blue shift of the absorption band as unstable-Z is converted to stable-Z. The helicity is inverted in this step, and as a result the sign of the CD absorption belonging to the **π–π*** band is changed. Subsequent irradiation of this sample with \( \lambda_{\text{max}} = 365 \) nm light yields the unstable E-isomer, which is again accompanied by a character-

\(^b\)Value determined at −94 °C.

UV/vis studies of motor 2 showed the same spectral changes as for motor 1, with a bathochromic shift upon irradiation of the stable E isomer (Figure S14). In this case, isomerization was observed upon irradiation with wavelengths up to \( \lambda_{\text{max}} = 505 \) nm, well into the visible region. Characterization of the isomerization behavior of motor 4 with UV/vis is more challenging due to its fast THI steps. Nonetheless, a bathochromic shift could be observed upon irradiation with wavelengths up to \( \lambda_{\text{max}} = 455 \) nm at −30 °C, most likely originating from the unstable E isomer (Figure S15). The unstable Z isomer undergoes THI which is too fast to follow at −30 °C (note that the calculated half-life at −30 °C is 38 ms).

Eyring analysis was performed to determine the activation parameters of the THIs of motors 1, 2, and 4. For compounds 1 and 2 the rate of THI was determined by following the change in absorbance at \( \lambda = 470 \) nm (see Figure S16 in the Supporting Information for details). For motor 4, low temperature \(^1\)H NMR was used to follow the conversion of the unstable state to the stable state (see Figure S21 in the Supporting Information for details). In each case, the rate of THI was determined at five temperatures, after which the activation parameters were obtained by using the Eyring equation (Table 2, Figures S16–S20). Due to its high rate, the

determined by following the absorption increase at λ = 475 nm upon irradiation of a sample with a high enough concentration to absorb all incident light. To assess the efficiency of these motors with visible light, \( \lambda_{\text{max}} = 420 \, \text{nm} \) irradiation was used. The rates thus obtained were then compared to the rate of formation of Fe(III) from potassium ferrioxalate under identical condition to estimate the quantum yields (Table 3; see Figures S22–S26 for details). The quantum yield for the reverse photochemical isomerization (\( \Phi_{\text{rev}} \)) could then be calculated using the PSS\( _{420} \) ratio and extinction coefficients (Table S1) at this wavelength.

### CONCLUSION

In summary, readily accessible molecular motors based on oxindole have been presented that can be driven by visible light. A four-step rotation cycle was proposed based on DFT calculations and confirmed by a combination of NMR, UV/vis, and CD spectroscopy. Motors with four different upper halves were easily synthesized by a Knoevenagel condensation, allowing tuning of the half-life for THI and the overall motor speed from the millisecond regime to multiple days. Additionally, the oxindole scaffold provides a versatile handle for further functionalization, opening up new possibilities for application in biology and materials science.
