Measurement of the CP-violating phase $\phi_s$ from $B^0_S \rightarrow J/\psi \pi^+\pi^-$ decays in 13 TeV $pp$ collisions

LHCb Collaboration

1. Introduction

Measurements of CP violation in final states that can be populated both by direct decay and via mixing provide an excellent way of looking for physics beyond the Standard Model (SM) [1]. As yet unobserved heavy bosons, light bosons with extremely small couplings, or fermions can be present virtually in quantum loops, and thus affect the relative CP phase. Direct decays into non-flavour-specific final states can interfere with those that undergo $B^0_S \rightarrow B^0 \rightarrow J/\psi \pi^+\pi^-$ mixing prior to decay. This interference can result in CP violation. In certain $B^0_S$ decays one CP-violating phase that can be measured, called $\phi_s$, can be expressed in terms of Cabibbo–Kobayashi–Maskawa matrix elements as $-2\arg \left[ V_{tb}^\ast V_{ts} / V_{cb}^\ast V_{cs} \right]$. It is not predicted in the SM, but can be inferred with high precision from other experimental data giving a value of $-36.5^{+13.2}_{-12.5}$ mrad [2]. This number is consistent with previous measurements, which did not have enough sensitivity to determine a non-zero value [3–7]. In this paper we present the results of a new analysis of the $B^0_S \rightarrow J/\psi \pi^+\pi^-$ decay using data from 13 TeV $pp$ collisions collected using the LHCb detector in 2015 and 2016. The existence of this decay and its use in CP-violation studies was suggested in Ref. [8].

2. Detector and simulation

The LHCb detector [9,10] is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, designed for the study of particles containing $b$ or $c$ quarks. The detector includes a high-precision tracking system consisting of a silicon-strip detector surrounding the $pp$ interaction region [11], a large-area silicon-strip detector located upstream of a dipole magnet with a bending power of about 4 m, and three stations of silicon-strip detectors and straw drift tubes placed downstream of the magnet. The tracking system provides a measurement of the momentum, $p$, of charged particles with a relative uncertainty that varies from 0.5% at low momentum to 1.0% at 200 GeV. The minimum distance of a track to a primary vertex (PV), the impact parameter (IP), is measured with a resolution of $(15+29/p_T)$ μm, where $p_T$ is the component of the momentum transverse to the beam, in GeV. Different types of charged hadrons are distinguished using information from two ring-imaging Cherenkov detectors [12]. Photons, electrons and hadrons are identified by a calorimeter system consisting of scintillating-pad and preshower detectors, an electromagnetic and a hadronic calorimeter. Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers [13]. The online event selection is performed by a trigger, which consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage, which applies a full event reconstruction.

At the hardware trigger stage, events are required to have a muon with high $p_T$ or a hadron, photon or electron with high transverse energy in the calorimeters. The software trigger is composed of two stages, the first of which performs a partial reconstruction and requires either a pair of well-reconstructed, oppo-
sitely charged muons having an invariant mass above 2.7 GeV, or a single well-reconstructed muon with $p_T > 1$ GeV and have a large IP significance $X^2_0 > 7.4$. The latter is defined as the difference in the $x^2$ of the vertex fit for a given PV reconstructed with and without the considered particles. The second stage applies a full event reconstruction and for this analysis requires two opposite-sign muons to form a good-quality vertex that is well-separated from all of the PVs, and to have an invariant mass within $\pm 120$ MeV of the known $J/\psi$ mass [14].

Simulation is required to model the effects of the detector acceptance and the imposed selection requirements. In the simulation, $pp$ collisions are generated using PYTHIA [15] with a specific LHCb configuration [16]. Decays of unstable particles are described by EvtGen [17], in which final-state radiation is generated using Photos [18]. The interaction of the generated particles with the detector, and its response, are implemented using the GEANT4 toolkit [19] as described in Ref. [20].

3. Decay amplitude

The resonance structure in $B^0 \to J/\psi \pi^+ \pi^- \pi^0$ decays has been previously studied with a time-integrated amplitude analysis using 7 and 8 TeV $pp$ collisions [21]. The final state was found to be compatible with being entirely CP-odd, with the CP-even state fraction below 2.3% at 95% confidence level, which allows the determination of the decay width of the heavy $B^0$ mass eigenstate, $\Gamma_{H}$. The possible presence of a CP-even component is taken into account when determining $\phi$ [22].

The total decay amplitude for a $B^0$ meson at decay time equal to zero is assumed to be the sum over individual $\pi^+ \pi^- \pi^0$ resonant transversity amplitudes [23], and one nonresonant amplitude, with each transversity component labelled as $A_i (A_{i})$. Because of the spin-1 $J/\psi$ meson in the final state, the three possible polarizations of the $J/\psi$ generate longitudinal (2), parallel (|), and perpendicular (⊥) transversity amplitudes. When the $\pi^+ \pi^- \pi^0$ form a spin-0 state the final system only has a longitudinal component, and thus is a pure CP eigenstate. The parameter $\lambda_i = \frac{q}{p} \vec{p}$. relates CP violation in the interference between mixing and decay associated with the polarization state $i$ for each resonance in the final state. Here the quantities $q$ and $p$ relate the mass and flavour eigenstates, $p \equiv (B^0|B_L)$, and $q \equiv (B^0|B_S)$, where $|B_L$ is the lighter mass eigenstate [1]. The total amplitudes $A$ and $\overline{A}$ can be expressed as the sum of the individual $B^0_i$ amplitudes, $A = \sum A_i$, and $\overline{A} = \sum \overline{A}_i = \sum \overline{A}_i = \sum \eta_i |\lambda_i| e^{-i\phi_i} A_i$, with $\eta_i$ being the CP eigenvalue of the state. For each transversity state $i$ there is a CP-violating phase $\phi_i = -\arg(\eta_i\lambda_i)$ [24]. Assuming that CP violation in the decay is the same for all amplitudes, then $\lambda = \eta = \lambda_i \lambda_i$ and $\phi_i = -\arg(\lambda_i)$. Using $|p/q| = 1$, the decay rates for $B^0$ and $\overline{B}^0$ into the $J/\psi \pi^+ \pi^- \pi^0$ final state are

$$\Gamma(t) \propto e^{-\Gamma t} \left\{ |A|^2 + |\overline{A}|^2 \cos \frac{\Delta t}{2} \pm |A|^2 - |\overline{A}|^2 \cos(\Delta m t) \right\},$$

$$\Gamma(t) \propto e^{-\Gamma t} \left\{ \frac{\Delta t}{2} \pm \frac{\Delta t}{2} \right\},$$

(1)

where the sign before the $\cos(\Delta m t)$ term and sign before the $\sinh(\Delta m t)$ term apply to $\overline{\Gamma}(t)$, $\Gamma_{H} \equiv \Gamma_{1} - \Gamma_{11}$ is the decay-width difference between the light and the heavy mass eigenstates, $\Delta m_i = m_{H} - m_{1}$ is the corresponding mass difference, and $\Gamma_{1} \equiv (\Gamma_{1} + \Gamma_{11})/2$ is the average $B^0$ meson decay width [26].

For $J/\psi$ decays to $\mu^+ \mu^-$ final states the $A_i$ amplitudes are themselves functions of four variables: the $\pi^+ \pi^- \pi^0$ invariant mass $m_{\pi\pi}$, and three angular variables $\Omega = (\cos \theta_{\pi\pi}, \cos \phi_{\pi\pi}, \chi)$, defined in the helicity basis. These angles are defined as $\theta_{\pi\pi}$ between the $\pi^+$ direction in the $\pi^+ \pi^- \pi^0$ rest frame with respect to the $\pi^+ \pi^- \pi^0$ direction in the $B^0$ rest frame, $\phi_{\pi\pi}$ between the $\mu^+$ direction in the $J/\psi$ rest frame with respect to the $J/\psi$ direction in the $B^0$ rest frame, and $\chi$ between the $J/\psi$ and $\pi^+ \pi^- \pi^0$ decay planes in the $B^0$ rest frame [22,24]. These definitions are the same for $B^0_S$ and $\overline{B}^0_S$, namely, using $\pi^+$ and $\pi^-$ to define the angles for both $B^0_S$ and $\overline{B}^0_S$ decays. The explicit forms of the $\{A(m_{\pi\pi}, \Omega)\}$, $\{\overline{A}(m_{\pi\pi}, \Omega)\}$, and $\{A^+(m_{\pi\pi}, \Omega), A^0(m_{\pi\pi}, \Omega)\}$ terms in Eq. (1) are given in Ref. [22].

The analysis proceeds by performing an unbinned maximum-likelihood fit to the $\pi^+ \pi^- \pi^0$ mass distribution, the decay time, and helicity angles of $B^0_S$ candidates identified as $B^0_S$ or $\overline{B}^0_S$ by a flavour-tagging algorithm [27]. The fit provides the CP-even and CP-odd components, and since we include the initial flavour tag, the fit also determines the CP-violating parameters $\phi$ and $\lambda$, and the decay width. In order to proceed, we need to select a clean sample of $B^0_S$ decays, determine acceptance corrections, perform a calibration of the decay-time resolution in each event as a function of its uncertainty, and calibrate the flavour-tagging algorithm.

4. Selection requirements

The selection of $J/\psi \pi^+ \pi^- \pi^0$ right-sign (RS), and wrong-sign (WS) $J/\psi \pi^+ \pi^- \pi^0$ final states, proceeds in two phases. Initially we impose loose requirements and subsequently use a multivariate analysis to further suppress the combinatorial background. In the first phase we require that the $J/\psi$ decay tracks be identified as muons, have $p_T > 500$ MeV, and form a good vertex with vertex fit $\chi^2$ less than 16. The identified pions are required to have $p_T > 250$ MeV, not originate from any PV, and form a good vertex with the muons. The resulting $B^0_S$ candidate is assigned to the PV for which it has the smallest $\chi^2_{IP}$. Furthermore, we require that the smallest $\chi^2_{IP}$ is not greater than 25. The $B^0_S$ candidate is required to have its momentum vector aligned with the vector connecting the PV to the $B^0_S$ decay vertex, and to have a decay time greater than 0.3 ps. Reconstructed tracks sharing the same hits are vetoed.

In addition, background from $B^+ \to J/\psi K^+$ decays, where the $K^+$ is misidentified as a $\pi^+$ and combined with a random $\pi^0$, is vetoed by assuming that each detected pion is a kaon, computing the $J/\psi K^{*+}$ mass, and removing those candidates that are within $\pm 36$ MeV of the known $B^+$ mass [14]. Backgrounds from $B^0 \to J/\psi K^{+} \pi^- \pi^0$ or $\overline{B}^0 \to J/\psi K^+ K^-$ decays with misidentified kaons result in masses lower than the $B^0_S$ peak and thus do not need to be vetoed.

For the multivariate part of the selection, we use a Boosted Decision Tree, BDT [28,29], with the uBoost algorithm [30]. The algorithm is optimized to not further bias acceptance on the variable $\cos \theta_{\pi\pi}$. The variables used to train the BDT are the difference between the muon and pion identifications for the muon identified with lower quality, the $p_T$ of the $B^0_S$ candidate, the sum of the $p_T$ of the two pions, and the natural logarithms of the $\chi^2_{IP}$ of each of the pions, the $\chi^2$ of the $B^0_S$ vertex and decay tree fits [31], and the $\chi^2_{IP}$ of the $B^0_S$ candidate. In the fit, the $B^0_S$ momentum vector is constrained to point to the PV, the two muons are constrained to

5 We utilize the same likelihood construction that we used to determine $\phi$ and $\lambda$ in $B^0 \to J/\psi K^+ K^-$ decays with $K^* K^+$ above the $f_{1}(1200)$ mass region [6].

6 When discussing flavour-specific decays, mention of a particular mode implies the additional use of the charge-conjugate mode.
The correlated efficiencies in \( m_{J/\psi \pi} \) and angular variables \( \Omega \) are determined from simulation. We weight the simulated signal events to reproduce the \( B^0 \) meson \( p_T \) and \( \eta \) distributions as well as the track multiplicity of the events. The latter may influence the efficiencies of the tracking and particle identification. The calculated efficiencies are shown in Fig. 2 along with the determined efficiency function. The four-dimensional efficiency is parameterized by a combination of Legendre and spherical harmonic moments [33], as

\[
\varepsilon(m_{J/\psi \pi}, \cos \theta_{J/\psi \pi}, \cos \theta_{J/\psi}, \chi) = \sum_{a,b,c,d} \varepsilon^{abcd} P_a(\cos \theta_{J/\psi \pi}) Y_{bc}(\theta_{J/\psi}, \chi) P_d \left( \frac{m_{J/\psi \pi} - m_{J/\psi \pi}^{\min}}{m_{J/\psi \pi}^{\max} - m_{J/\psi \pi}^{\min}} - 1 \right),
\]

where \( P_a \) and \( P_d \) are Legendre polynomials, \( Y_{bc} \) are spherical harmonics, \( m_{J/\psi \pi}^{\min} = 2m_{\eta} \) and \( m_{J/\psi \pi}^{\max} = m_{J/\psi} - m_{\pi^0} \), and \( \varepsilon^{abcd} \) are efficiency coefficients determined from weighted averages of decays generated uniformly over phase space [6].

The model gives an excellent representation of the simulated data. The efficiency is uniform within about \( \pm 4\% \) for \( \cos \theta_{J/\psi} \) and about \( 10\% \) for \( \chi \) variables; however the \( m_{J/\psi \pi} \) and \( \cos \theta_{J/\psi \pi} \) variables show large efficiency variations and correlations (see Fig. 3), due to the \( \chi^2_T > 4 \) requirements on the hadrons. The loss of efficiency in the lower \( m_{J/\psi \pi} \) region can be interpreted as the projection of the effects of cuts on \( \chi^2_T \). Events at \( \cos \theta_{J/\psi \pi} = \pm 1 \) and \( m_{J/\psi \pi} \approx 0.6 - 0.8 \) GeV are at the kinematic boundary of \( m_{J/\psi \pi}^{\max} \). One of the pions is almost at rest in \( B^0 \) rest frame, and thus the pion points to the PV, resulting in a very small \( \chi^2_T \) for this pion. The \( \chi^2_T \) variable is the most useful tool to suppress large pion combinatorial background from the PV.

The reconstruction efficiency is not constant as a function of \( B^0 \) decay time due to displacement requirements applied to the hadrons in the offline selections and on \( J/\psi \) candidates in the trigger. It is determined using the control channel \( B^0 \to J/\psi K^{*(892)^0} \), with \( K^{*(892)^0} \to K^+ \pi^- \), which is known to have a lifetime of \( \tau_{K^{*(892)^0}} = 1.520 \pm 0.004 \) ps [14]. The simulated \( B^0 \) events are weighted to reproduce the distributions in the data for \( p_T \) and \( \eta \) of the \( B^0 \) meson, and the invariant mass and helicity angle of \( K^+ \pi^- \) system, as well as the track multiplicity of the events. The signal efficiency is calculated as \( \varepsilon_{data}(t) = \varepsilon_{data}(t = 0) \cdot \varepsilon_{sim}(t)/\varepsilon_{sim}(t) \), where \( \varepsilon_{data}(t) \) is the efficiency of the control channel as measured by comparing data with the known lifetime distribution, and \( \varepsilon_{sim}(t)/\varepsilon_{sim}(t) \) is the ratio of efficiencies of the simulated signal and control mode after the full trigger and selection chain have been applied. This correction accounts for the small differences in the kinematics between the signal and control modes. The details of the method are explained in Ref. [4].

The acceptance is checked by measuring the decay width of \( B^0 \to J/\psi K^+ \) decays. The fitted decay-width difference between the \( B^+ \) and \( B^0 \) mesons is \( \Gamma_{B^+} - \Gamma_{B^0} = -0.0475 \pm 0.0013 \) ps\(^{-1} \), where the uncertainty is statistical only, in agreement with the known value of \( -0.0474 \pm 0.0023 \) ps\(^{-1} \) [14].

From the measured \( B^0 \) candidate momentum and decay distance, the decay time and its event-by-event uncertainty \( \delta t \) are calculated. The calculated uncertainty is imbedded into the resolution function, which is modeled by the sum of three Gaussian functions with common means and widths proportional to a quadratic function of \( \delta t \). The parameters of the resolution function are determined with a sample of putative prompt \( J/\psi \to \mu^+ \mu^- \).
decays combined with two pions of opposite charge. Taking into account the decay-time uncertainty distribution of the $B^0_s$ signal, the average effective resolution is found to be 41.5 fs. The method is validated using simulation; we estimate the accuracy of the resolution determination to be ±3%.

6. Flavour tagging

Knowledge of the $B^0_s$ flavour at production is necessary. We use information from decays of the other $b$ hadron in the event (opposite-side, OS) and fragments of the jet that produced the $B^0_s$ meson that contain a charged kaon, called same-side kaon (SSK) [27]. The OS tagger infers the flavour of the other $b$ hadron in the event from the charges of muons, electrons, kaons, and the net charge of the particles that form reconstructed secondary vertices.

The flavour tag, $q$, takes values of +1, −1 or 0 if the signal meson is tagged as $B^0_s$, $B^0_s$ or untagged, respectively. The wrong-tag probability, $\eta$, is estimated event-by-event based on the output of a neural network. It is subsequently calibrated with data in order to relate it to the true wrong-tag probability of the event by a linear relation as

$$\omega(\eta) = p_0 + \frac{\Delta p_0}{2} + \left(p_1 + \frac{\Delta p_1}{2}\right) \cdot (\eta - \langle \eta \rangle);$$

$$\bar{\omega}(\eta) = p_0 - \frac{\Delta p_0}{2} + \left(p_1 - \frac{\Delta p_1}{2}\right) \cdot (\eta - \langle \eta \rangle).$$

where $p_0$, $p_1$, $\Delta p_0$ and $\Delta p_1$ are calibration parameters, and $\omega(\eta)$ and $\bar{\omega}(\eta)$ are the calibrated probabilities for a wrong-tag assignment for $B^0_s$ and $B^0_s$ mesons, respectively. The calibration is performed separately for the OS and the SSK taggers using $B^+ \rightarrow J/\psi K^+$ and $B^0_s \rightarrow D^- \pi^+$ decays, respectively. When events are tagged by both the OS and the SSK algorithms, a combined tag decision is formed. The resulting efficiency and tagging powers are listed in Table 1.

![Fig. 2. Overall efficiency normalized to unity for (a) $m_{\pi\pi}$, (b) $\cos \theta_{\pi\pi}$, (c) $\cos \theta_{\eta}$ and (d) $\chi$ observables. 7. Description of the $\pi^+\pi^-$ mass spectrum

We fit the entire $\pi^+\pi^-$ mass spectrum including the resonance contributions listed in Table 2, and a nonresonant (NR) component. We use an isobar model [21]. All resonances are described by Breit–Wigner amplitudes, except for the $f_0(980)$ state, which is modelled by a Flatté function [34]. The nonresonant amplitude is treated as being constant in $m_{\pi\pi}$. Other theoretically motivated amplitude models are also proposed to describe this decay [35, 36]. The previous publication [21] used an unconfirmed $f_0(1790)$ resonance, reported by the BES collaboration [37], instead of the $f_0(1710)$ state. We test which one gives a better fit.

The amplitude $A_R(m_{\pi\pi})$, generally represented by a Breit–Wigner function or a Flatté function, is used to describe the mass line shape of resonance $R$. To describe the resonance from the $B^0_s$ decays, the amplitude is combined with the $B^0_s$ and resonance decays properties to form the following expression

$$A_R(m_{\pi\pi}) = \sqrt{2} J_R + \sqrt{P_R P_B} F_{LB}^{(L_B)} F_{LR}^{(L_R)} A_R(m_{\pi\pi}) \times \left( \frac{P_B}{m_B} \right)^{L_B} \left( \frac{P_R}{m_R} \right)^{L_R} A_R(m_{\pi\pi}).$$

(4)

8. Likelihood definition

The decay-time distribution including flavour tagging is

$$R(\hat{t}, m_{\pi\pi}, \Omega, \varepsilon(\eta)) = \frac{1}{1 + |\varepsilon(\eta)|} \left[ 1 + Q(1 - 2i\omega(\eta)) \right] \Gamma(\hat{t}, m_{\pi\pi}, \Omega) + \left[ 1 - Q(1 - 2i\omega(\eta)) \right] \frac{1 + A_P}{1 - A_P} \Gamma(\hat{t}, m_{\pi\pi}, \Omega),$$

(5)

where $\hat{t}$ is the true decay time, $\omega(\eta)$ is defined in Eq. (1), and $A_P$ is the production asymmetry of $B^0_s$ mesons.

The fit function for the signal is modified to take into account the decay-time resolution and acceptance effects resulting in

$$F(t, m_{\pi\pi}, \Omega, \varepsilon(\eta), \delta_t) = \left[ R(\hat{t}, m_{\pi\pi}, \Omega, \varepsilon(\eta)) \otimes T(t - \hat{t}(\eta)) \right] e^{\theta_0} e^{\delta_s(t)} e^{\delta_r(t)} e_{\text{data}}(t) \varepsilon(m_{\pi\pi}, \Omega),$$

(6)

where $\varepsilon(m_{\pi\pi}, \Omega)$ is the efficiency as a function of $m_{\pi\pi}$ and angular variables, $T(t - \hat{t}(\eta))$ is the decay-time resolution function, and $e^{\theta_0} e^{\delta_s(t)} e^{\delta_r(t)} e_{\text{data}}(t)$ is the decay-time acceptance function. The free parameters in the fit are $\phi_s, |\lambda|, \Gamma_{\pi\pi} - \Gamma_{\pi\pi}$, the magnitudes and phases of the resonances amplitudes, and the shape parameters of some resonances. The other parameters, including $\Delta m_\pi$ and $\Gamma_{\pi\pi}$, are fixed to the known values [14] or other measurements mentioned below.

The signal function is normalized by summing over $\eta$ values and integrating over decay time $t$, the mass $m_{\pi\pi}$, and the angular variables, $\Omega$, giving

$$N(\delta_t) = 2 \int \left[ \Gamma(\hat{t}, m_{\pi\pi}, \Omega) + \frac{1 + A_P}{1 - A_P} \Gamma(\hat{t}, m_{\pi\pi}, \Omega) \right] \otimes T(t - \hat{t}(\eta)) e^{\theta_0} e^{\delta_s(t)} e^{\delta_r(t)} e_{\text{data}}(t) \varepsilon(m_{\pi\pi}, \Omega) \, dm_{\pi\pi} \, d\Omega dt. $$

(7)

We assume no asymmetries in the tagging efficiencies, which are accounted for in the systematic uncertainties. The resulting signal PDF is

$$P(t, m_{\pi\pi}, \Omega, \varepsilon(\eta), \delta_t) = \frac{1}{N(\delta_t)} F(t, m_{\pi\pi}, \Omega, \varepsilon(\eta), \delta_t).$$

(8)

The fitter uses a technique similar to sPlot [40] to subtract background from the log-likelihood sum. Each candidate is assigned a weight, $W_i = +1$ for the RS events and negative values for the WS events. The likelihood function is defined as

$$-2 \ln L = -2 s_W \sum_i W_i \ln P(t, m_{\pi\pi}, \Omega, \varepsilon(\eta), \delta_t),$$

(9)

where $s_W \equiv \sum_i W_i / \sum_i W_i^2$ is a constant factor accounting for the effect of the background subtraction on the statistical uncertainty.

The decay-time acceptance is assumed to be factorized from other variables, but due to the $\chi^2_2$ cut on the two pions, the decay time is correlated with the angular variables. To avoid bias on the determination of $\Gamma_{\pi\pi}$ from the decay-time acceptance, the simulated $B^0_s$ signal is weighted in order to reproduce the $m_{\pi\pi}$ resonance structure observed in data by using the preferred amplitude model that is determined by the overall fit. An iterative procedure is performed to finalize the decay-time acceptance. This procedure converges in three steps beyond which $\Gamma_{\pi\pi}$ does not vary. When we apply this method to pseudoexperiments that include the correlation mentioned before, the fitter reproduces the input values of $\phi_s, \Gamma_{\pi\pi}$, and $|\lambda|$.

Table 4
Fit results for the $CP$-violating parameters for Solution I. The first uncertainties are statistical, and the second systematic. The last three columns show the statistical correlation coefficients for the three parameters.

| Parameter | $\Gamma_\pi - \Gamma_{\psi}$ (ps$^{-1}$) | $|\lambda|$ | $\phi_\lambda$ | $\phi_\lambda$ |
|-----------|---------------------------------------|-------------|---------------|---------------|
| $\Gamma_\pi - \Gamma_{\psi}$ (ps$^{-1}$) | $-0.050 \pm 0.004 \pm 0.004$ | $1.000$ | $0.022$ | $0.038$ |
| $|\lambda|$ (rad) | $1.013\pm0.06 \pm 0.03$ | $0.022$ | $1.000$ | $0.065$ |
| $\phi_\lambda$ (rad) | $-0.057 \pm 0.060 \pm 0.011$ | $0.038$ | $0.065$ | $1.000$ |

Fig. 4. Projections of the angular and decay-time variables with the fit result overlaid. The points (black) show the data and the curves (blue) the fits.

Fig. 5. Data distribution of $m_{\pi\pi}$ with the projection of the Solution I fit result overlaid. The data are described by the points (black) with error bars. The solid (blue) curve shows the overall fit.

9. Fit results

We first choose the resonances that best fit the $m_{\pi\pi}$ distribution. Table 3 lists the different fit components and the value of $-2\ln L$. In these comparisons, the mass and width of most resonances are fixed to the central values listed in Table 2, except for the $f_0(980)$ and $f_0(1500)$ resonances, whose parameters are allowed to vary. We find two types of fit results, one with a positive integrated sum of all interfering components and one with a negative one. The first listed Solution I is better than Solution II by four standard deviations, calculated by taking the square root of the $-2\ln L$ difference. We take Solution I for our measurement and II for systematic uncertainty evaluation. The models corresponding to Solutions I and II are very similar to those found in our previous analysis of the same final state [21].

For the fit we assume that the $CP$-violation quantities ($\phi_\lambda$, $|\lambda|$) are the same for all the resonances. We also fix $\Delta\mu$ to the central value of the world average $17.757 \pm 0.021$ ps$^{-1}$ [14], and fix $\Gamma_\pi$ to the central value of $0.6995 \pm 0.0047$ ps$^{-1}$ from the LHCb $B^0 \rightarrow J/\psi K^+K^-$ results [6].

The fit values and correlations of the $CP$-violating parameters are shown in Table 4 for Solution I. The shape parameters of $f_0(980)$ and $f_0(1500)$ resonances are found to be consistent with our previous results [21]. The angular and decay-time fit projections are shown in Fig. 4. The $m_{\pi\pi}$ fit projection is shown in Fig. 5, where the contributions of the individual resonances are also displayed. All solutions listed in Table 3 give very similar fit values for $\phi_\lambda$ and $\Gamma_\pi$. We also find that the $CP$-odd fraction is greater than $97\%$ at $95\%$ confidence level. The resonant content for Solutions I and II are listed in Table 5.
10. Systematic uncertainties

The systematic uncertainties for the CP-violating parameters, λ and φ2, are smaller than the statistical ones. They are summarized in Table 6 along with the uncertainty on ΓH − Γ0. The uncertainty on the decay-time acceptance is found by varying the parameters of the acceptance function within their uncertainties and repeating the fit. The same procedure is followed for the uncertainty on the B0 lifetime, ΓH, mαππ, and angular efficiencies, resonance masses and widths, flavour-tagging calibration, and allowing for a 2% production asymmetry [41]; this uncertainty also includes any possible difference in flavour tagging between B+ and B0. Simulation is used to validate the method for the time-resolution simulation. The uncertainties of the parameters of the time-resolution model are estimated using the difference between the signal simulation and prompt J/ψ simulation. These uncertainties are varied to obtain the effects on the physics parameters. Resonance modelling uncertainty includes varying the Breit–Wigner barrier factors, changing the default values of L0 = 1 for the D-wave resonances to one or two, the differences between the two best solutions, and replacing the NR component by the f0(500) resonance. Furthermore, including an isospin-violating ρ(770) component in the fit, results in a negligible contribution of (1.1 ± 0.3)%. The largest shift among the modelling variations is taken as systematic uncertainty. The inclusion of ρ components results in the largest shifts of the three physics parameters quoted. The process B+ → π+π0 can affect the measurement of ΓH − Γ0. An estimate of the fraction of these decays in our sample is 0.8% [5]. Neglecting the B+ contribution leads to a bias of 0.0005 ps−1, which is added as a systematic uncertainty. Other parameters are unchanged.

Corrections from penguin amplitudes are ignored because their effects are known to be small [42–44] compared to the current experimental precision.

11. Conclusions

Using B0 and B+ → J/ψ π+π− decays, we measure the CP-violating phase, φ2 = −0.057 ± 0.060 ± 0.011 rad, the decay-width difference ΓH − Γ0 = −0.050 ± 0.004 ± 0.004 ps−1, and the parameter |λ| = 1.01±0.08 ± 0.03, where the quoted uncertainties are statistical and systematic. These results are more precise than those obtained from the previous study of this mode using 7 TeV and 8 TeV pp collisions (Run 1) [4]. To combine the Run-1 results with these, we reanalyze them by fixing Δmπ = 17.75 ± 0.021 ps−1 from Ref. [14], and Γ1 = 0.6995 ± 0.0047 ps−1 from the LHCb B+ → J/ψ K+K− results [6]. We remove the Gaussian constraint on ΔΓ1 and let Γ1 vary. Instead of taking the uncertainties of flavour tagging and decay-time resolution into the statistical uncertainty, we place these sources in the systematic uncertainty and assume 100% correlation with our new results. The updated results are: φ2 = 0.075 ± 0.065 ± 0.014 rad and |λ| = 0.898 ± 0.051 ± 0.013 with a correlation of 0.025. We then use the updated φ2 and |λ| Run-1 results as a constraint into our new φ2 fit. The combined results are ΓH − Γ0 = −0.050 ± 0.004 ± 0.004 ps−1, |λ| = 0.949 ± 0.036 ± 0.019, and φ2 = 0.002 ± 0.044 ± 0.012 rad. The correlation coefficients among the fit parameters are 0.025 (ρ12), −0.001 (ρ13), and 0.026 (ρ23).

Our results still have uncertainties greater than the SM prediction and are slightly more precise than the measurement using B+ → J/ψ K+K− decays, based only on Run-1 data, which has a precision of 0.049 rad [5]. Hence this is the most precise determination of φ2 to date.

Acknowledgements

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); MOST and NSFC (China); CNRS/IN2P3 (France); BMBF, DFG and MPG (Germany); INFN (Italy); NWO (Netherlands); MNiSW and NCN (Poland); MEN/IFA (Romania); MSHE (Russia); MINECO (Spain); SNSF and SER (Switzerland); NASU (Ukraine); STFC (United Kingdom); NSRF (USA).
