**Abstract**

Methotrexate (MTX) is a cytostatic agent widely used in combination with other agents as adjuvant chemotherapy for breast cancer and is associated with cognitive impairment as a long-term side effect in some cancer patients. This paper aimed to identify a neurobiological mechanism possibly responsible for this cognitive impairment using an animal model.

The first study explored the hypothesis that MTX reduces neuronal cell proliferation. A dose-dependent long-lasting decrease in hippocampal cell proliferation was shown with Ki-67 immunocytochemistry, following a single intravenous injection of MTX (37.5 – 300 mg/kg). Animals treated with MTX also showed a dose-dependent transient decrease in body weight gain.

In the second study, the effect of MTX (250 mg/kg) on two spatial learning tasks was examined. Animals treated with MTX learned the Morris water maze task adequately; however, these animals showed a longer latency time to cross the platform location in the probe trial, reflecting an impairment of spatial memory function. In the novel object recognition task, animals treated with MTX failed to distinguish a novel object from a familiar one, indicating a decrease in the comparator function of the hippocampus.

Our studies indicated that, in the rat, MTX has a dose-dependent negative effect on hippocampal cell proliferation, and on cognitive behavior. These findings suggest that adverse effects of certain cytotoxic agents on hippocampal cell proliferation may have a potential contributory role in cognitive impairment observed in humans after chemotherapy.

**Introduction**

Cytostatic drugs are often applied in modern oncology; patients live longer and even survive. Hence, increasing attention is paid to negative side effects. In several neuropsychological and neurophysiological studies, cognitive impairment is consistently observed in a subgroup of patients treated with various regimens of adjuvant chemotherapy for breast cancer (CMF1, CTC2, FEC3) (Ahles et al., 2002; Brezden et al., 2000; Castellon et al., 2004; Kreukels et al., 2005; Schagen et al., 1999; Schagen et al., 2001; Schagen et al., 2006; Shilling et al., 2005; Van Dam et al., 1998; Wefel et al., 2004). These deficits range from very subtle to more severe and are observed in a wide range of brain functions, including memory, concentration, and speed of information processing (Kreukels et al., 2005), and can be noticed up to ten years after completion of cytotoxic treatment (Ahles et al., 2002). Recently, a clinical study was performed in which the effect of CMF chemotherapy on grey and white matter volume was examined. People who had received adjuvant chemotherapy showed smaller grey and white matter volume in the prefrontal and parahippocampal gyrus one year after treatment, compared to those who had not received chemotherapy. These findings were significantly correlated with impairments in attention, concentration, and/or visual memory. Effects of chemotherapy on brain volume were not noticed three years after treatment (Inagaki et al., 2007).

Despite these indications of negative effects on the central nervous system resulting in persistent cognitive dysfunction, our understanding of the nature of the cognitive impairment and the underlying mechanisms is fragmentary at best. Due to the compound nature of the chemotherapeutic regimens, in humans it is difficult to isolate specific etiological agents responsible for the cognitive impairment

---

1 CMF regimen: cyclophosphamide, 100 mg/m² orally on days 1 to 14; methotrexate, 40 mg/m² intravenously on days 1 and 8; 5-fluorouracil, 600 mg/m² intravenously on days 1 and 8; repeated every four weeks
2 CTC regimen: cyclophosphamide, 6 g/m² intravenously; thiotepa, 480 mg/m² intravenously; carboplatin, 1.6 g/m² intravenously; divided over four days
3 FEC regimen: 5-fluorouracil, 500 mg/m² intravenously; epidoxorubicin, 90-120 mg/m² intravenously; cyclophosphamide, 500 mg/m² intravenously; repeated every three weeks
Animal models of human cognitive function might help elucidate the neural mechanisms mediating cytostatic brain damage.

In the few animal studies performed, mainly methotrexate (MTX), a frequently used cytotoxic agent in the clinic, was examined. Philips and colleagues showed that, after high-dose administration of MTX into the femoral vein in rats, several behavioral changes occurred including reduced spontaneous activity and diminished startle response to loud noise or vibrissal stimulation (Phillips et al., 1986). Another study investigating high-dose intraperitoneal injections of MTX showed enhanced occurrence of seizures in mice (possibly due to a lowering of GABA content), and an impairment of long-term memory in a passive avoidance task (Sieklucka-Dziuba et al., 1998).

A potential mechanism underlying the adverse effect on brain functioning but not yet studied is the effect of cytostatic drugs on neurogenesis. In the 1960s it was established that the production of new cells in the adult brain is not restricted to glial cells, but there is also a persistent production of neurons (Altman and Das, 1965). This neurogenesis has recently received much attention. Studies have shown that stem cells continuously produce new neurons in several brain areas, the most prominent ones being the subventricular zone (SVZ), which lines the lateral ventricles, and the sub granular zone (SGZ) of the hippocampal dentate gyrus (DG) (Gould et al., 2000; Kempermann et al., 2002). Since the hippocampal formation is well known for its involvement in learning and memory processes, it is suggested that neurogenesis in this brain structure plays a functional role in cognitive performance. Animals with lowered neurogenesis perform worse in hippocampal-dependent tasks and exhibit a learning impairment (Gould et al., 2000), whereas an enriched environment enhances neurogenesis, and increases learning capacity (Kempermann, 2002; Madsen et al., 2003). Since many cytotoxic compounds, like MTX, are aimed at the inhibition of the process of cell division, they will probably also affect cell proliferation in the brain if they are able to pass the blood-brain barrier. Although it is assumed that most cytotoxic agents do not pass the blood-brain barrier, MTX seems to be an exception (Dukic et al., 2000). Therefore, we hypothesize that due to MTX hippocampal cell proliferation is negatively affected, which may play a contributory role in the cognitive decline observed in some cancer patients.

We tested this hypothesis in two different studies. The first study determined the dose-response relationship between MTX and hippocampal cell proliferation. Since Ki-67 is a nuclear protein antigen involved in cell proliferation regulation (Rorstad, 2005), Ki-67 positive cells were immunocytochemically visualized and quantified in the SGZ by light microscopic analysis of brain sections 3 weeks after administration of the cytostatic drug.

The second study explored the effects of a high-dose MTX on cognitive performance in hippocampal-dependent learning tasks. Three weeks after treatment with MTX, animals were trained in the Morris water maze (MWM). Another group of animals was subjected to the novel object recognition (NOR) task, performed four weeks after treatment with MTX.

Methods

Adult (3 months of age) male Wistar rats (Harlan, Zeist, the Netherlands, average bodyweight at the start of the experiment 297.1 gram ± 11.67 SEM) were housed individually in clear Plexiglas cages (25 x 25 x 30 cm) on a layer of wood shavings with a fixed 12:12 h light:dark cycle with lights on at 08.00 a.m., and food and water ad libitum.

Experiments started 2 weeks after arrival of the animals according to the protocol described below. After injection with MTX (100 mg/ml, Pharmachemie BV, Haarlem, The Netherlands), animals received intraperitoneal injections of calcium leucovorin (10 mg/ml, Pharmachemie BV, Haarlem, The Netherlands), which is clinically used as a so-called rescue therapy in combination with the cytotoxic agent. Tetrahydrofolate (THFA) is a cofactor in DNA synthesis, MTX is an inhibitor of the enzyme
THFA reductase and depletes the pool of tetrahydrofolic acid. Leucovorin is a tetrahydrofolate and does not require activation by THFA reductase (Genestier et al., 2000; Huennekens, 1994). The rescue therapy of leucovorin was administered in a protocol similar to that applied in patients. Eighteen hours after the injection of MTX, leucovorin was administered in a concentration that was 8% of the injected MTX dosage; at 26, 42, and 50 hours the administered concentration was reduced to 4%. Pilot studies showed that leucovorin itself does not have an effect on neurogenesis and that high-dose MTX without leucovorin is lethal, due to severe diarrhea and weight loss.

All experiments were approved by the Animal Experimentation Committee of the University of Groningen.

**MTX dose-response interaction for body weight gain and hippocampal cell proliferation**

In the first study, rats were injected with various dosages of MTX (37.5, 75, 150 or 300 mg/kg) in the tail vein under a short-lasting (< 3 minutes) mild O₂-N₂O-isoflurane anesthesia. Control animals were injected with saline. Body weight of all animals was measured on a daily basis. The animals were sacrificed 3 weeks after the injection through transcardial perfusion with saline followed by 4% paraformaldehyde. Brains were removed and placed in 30% sucrose solution at 4°C. Microtome sections of the hippocampus (40 µm) were stored in 0.01 M PBS including azide until immunocytochemical staining.

From the serial sections, every twelfth section from each animal was selected and immunocytochemically stained for Ki-67 using a slightly adapted standard protocol (Kee et al., 2002). In brief, free-floating sections were pre-treated with 0.4% H₂O₂ for 30 minutes, to stop endogenous peroxidase activity. Non-specific binding of immunoreagents was blocked with 3% normal goat serum (Zymed, San Francisco, USA). Subsequently, sections were incubated with mouse-anti-Ki-67 (1:200, Novocastra, Newcastle upon Tyne, UK), for 48 hours at 4°C. After a second blocking step, sections were incubated with a biotinylated secondary antibody (1:400, goat-anti-mouse, Jackson, Wet Grove, PA, USA) for 2 hours at room temperature. This was followed by incubation in an avidin biotinylated peroxidase complex (1:400, ABC Elite Kit, Vector Laboratories, Burlingame, CA, USA). Labeled cells were visualized with 0.15 mg/ml diaminobenzidine (DAB) and 0.003% H₂O₂ solution.

After mounting of the sections onto glass slides for microscopic analysis, sections were counterstained with a Mayer-haematoxylin solution for 30 seconds. Counting of Ki-67 positive cells in both hemispheres of the dentate gyrus was performed under a light microscope with a magnification of 400x. Counting was performed in the subgranular layer of the dentate gyrus. Counts in both blades were summed. The borders of the area that was quantified was defined as the subgranular layer having a thickness of two cell diameters. All cells were counted in the subgranular layer of the dentate gyrus from top to bottom of the 40 µm thick section. Because every twelfth section of the brain was stained, the amount of positive cells was multiplied by 12 to get the estimated total amount of Ki-67 positive cells in the hippocampus.

**Effects of high-dosage MTX on cognitive performance**

In patients, MTX, in the dosage used as adjuvant chemotherapy in the CMF cocktail, induces a body weight loss of approximately 10% and mild diarrhea (Flombaum and Meyers, 1999). In order to achieve similar effects in animals and based on the effects of the dose-response interaction, we injected rats with 250 mg/kg MTX for the behavioral tasks, which were performed after the animals recovered from the sickness caused by MTX.

**Morris water maze learning**

Animals were injected with either saline or MTX (250 mg/kg) as previously described. Three weeks after treatment, the MWM task was performed, which tests spatial cognitive performance. The task was performed in a circular black pool (Ø 140 cm) with a black platform. The pool was filled with water of
26 ± 1 °C, so that the platform was about 1 cm below the water surface. The pool was surrounded with external, constant cues and the observer always sat in the same position. The task consisted of 5 training days with 2 trials per day with an inter-trial time of 1 hour. One trial lasted for 3 minutes or until the rat found the platform and sat on it for 10 seconds. If a rat did not find the platform within 3 minutes, it was guided by hand. On day 6, the platform was removed and the rat was placed in the pool for a probe trial which lasted 1 minute. Behavior of the animal was tracked by using Ethovision 3.0 and analyzed for escape latency in the learning phase, meaning the time from the beginning of the trial until the rat sat on the platform. During the probe trial, the time spent before the animal crossed the platform location was recorded.

Novel object recognition

Animals received an injection of either saline or MTX (250 mg/kg) as previously described. Four weeks after treatment, the comparator function of the hippocampus was tested in a NOR task. The task was performed in a wooden box (40 x 50 x 80 cm) without bedding. The animals received a habituation session on day 1 to explore the box without objects, lasting 3 minutes. Day 2 consisted of 2 trials, each lasting 3 minutes, with an inter trial time of 1 hour. In the first trial, the acquisition phase, two identical objects (Duplo Lego toys, cubes, 6.5 x 6.5 x 7 cm) were placed in the center of the box, 13 cm apart. In the second trial, the recollection phase, one object was replaced by a novel object, with a different shape and color (rectangle, 3 x 13 x 8 cm). Objects were securely fixed to the floor of the box using tape, so the animals could not move them around. The objects and the box were cleaned after each session with 70% alcohol. Exploration behavior of the different objects (sniffing or touching the objects), was analyzed using Eline 0.9. The discrimination index (in percentage) was defined as the time spent exploring the novel object divided by the time spent exploring the familiar object.

Statistics

Body weight was analyzed using repeated measure ANOVA. Light-microscopic counts of Ki-67 positive cells and the behavioral tasks were analyzed using one-way ANOVA with treatment as between-subject variable. LSD post-hoc test was performed when the ANOVA test was significant. For all statistical tests, a probability value less than 0.05 was considered to be statistically significant.

Results

MTX dose-response interaction for body weight and hippocampal cell proliferation

Body weight gain

Body weight gain was calculated as absolute body weight/absolute body weight on the day of the injection, multiplied by 100. For day 0 (the day of the injection), this will give a relative body weight of 100%; body weight gain is determined as the relative body weight that is more than 100%.

All rats showed a decrease in body weight gain after the injection (figure 1). Whereas the control animals and animals that received 37.5 mg/kg MTX regained their body weight on day 2, the other animals (75, 150 and 300 mg/kg MTX) continued to lose weight and suffered from mild diarrhea. After day 4, all animals recovered and started to regain body weight. The difference in body weight gain between the different treatments was significant, F_{4,60} = 3.057, P < 0.0001. The difference between the control animals and the animals treated with 37.5 and 75 mg/kg MTX was significant with P < 0.05. The difference between the control animals and the animals treated with 150 and 300 mg/kg MTX was also significant with P < 0.0001.
Hippocampal cell proliferation and cognitive performance

Figure 1: Body weight gain after intravenous administration of saline (○) or MTX (● 37.5 mg/kg; □ 75 mg/kg; ■ 150 mg/kg; △ 300 mg/kg; n = 6 per group). Body weight before the injection (given on day 0) is expressed as 100%, bars represent standard error of the mean. The difference in body weight gain between the different treatments was significant, $F_{4, 60} = 3.057$, $P < 0.0001$. The difference between the control animals and the animals treated with 37.5 and 75 mg/kg MTX 300 is significant with $P < 0.05$. The difference between the control animals and the animals treated with 150 and 300 mg/kg MTX is significant with $P < 0.0001$.

Ki-67 immunocytochemistry

Ki-67 positive cells in microtome sections of the hippocampus were visualized and counted. The average number of sections counted per animal per group was 11.75 ± 1.23 SEM, 12.00 ± 0.42 SEM, 11.81 ± 0.41 SEM, 11.13 ± 0.68 SEM, and 12.90 ± 0.62 SEM for the control animals and the animals treated with 37.5, 75, 150, and 300 mg/kg MTX, respectively.

The number of Ki-67 positive cells differed significantly between the groups, $F_{4, 23} = 6.822$, $P = 0.0009$ (figure 2). Control animals had significantly more Ki-67 positive cells in the hippocampus than animals treated with 37.5, 75 (both $P < 0.005$), 150 ($P < 0.001$) or 300 mg/kg ($P < 0.0001$). Two other groups, 37.5 and 75 mg/kg MTX, differ significantly from 300 mg/kg MTX ($P < 0.05$).

Figure 2: Total number of Ki-67 positive cells in the hippocampus of control rats (open bar) and animals treated with MTX (solid bar 37.5 mg/kg; diagonal striped bar 75 mg/kg; vertical striped bar 150 mg/kg; horizontal striped bar 300 mg/kg; n = 6 per group). Data are represented as mean with standard error of the mean. The number of Ki-67 positive cells differ significantly between the groups, $F_{4, 23} = 6.822$, $P = 0.0009$. Control animals have significantly more Ki-67 positive cells than animals treated with MTX (* $P < 0.05$; ** $P < 0.001$; *** $P < 0.0001$). Two other groups, 37.5 and 75 mg/kg MTX, differ significantly from 300 mg/kg MTX ($P < 0.05$).
Effects of high-dosage MTX on cognitive performance

Morris water maze learning

Three weeks after injection of 250 mg/kg MTX, a MWM task was performed. Figure 3 shows the daily average escape latency during the training period. All animals learned the location of the platform, with no significant differences between the groups. Control animals and animals treated with MTX both significantly improved during the learning phase, with $F_{4, 30} = 3.135, P < 0.05$; $F_{4, 40} = 4.508, P < 0.05$ respectively. However, animals treated with MTX showed a longer latency time to cross the platform area during the probe trial compared to control animals, $F_{1, 12} = 3.135, P < 0.05$ for both one-way ANOVA and post-hoc test (figure 4).

There was no difference in average swim speed or distance traveled between control animals and animals treated with MTX (data not shown).

Figure 3: The mean escape latency in the Morris water maze test for control animals (○) and animals treated with MTX (●, 250 mg/kg; n = 8 per group). The two trials per day are shown as average values with standard error of the mean. Control animals and animals treated with MTX both significantly improve during the learning phase, with $F_{4, 30} = 3.135, P < 0.05$; $F_{4, 40} = 4.508, P < 0.05$ respectively. No significant effects are seen between control animals and animals treated with MTX.

Figure 4: Latency time to cross the platform location in the probe trial in the Morris water maze test (n = 8 per group). Data are represented as mean with standard error of the mean. Animals treated with MTX (●, 250 mg/kg) show a longer latency time than control animals (○), $P < 0.05$. 
**Novel object recognition**

Four weeks after treatment with 250 mg/kg MTX, a NOR task was performed. Figure 5 shows the discrimination index (time spent exploring the novel object / time spent exploring the familiar object * 100) for the recollection phase. A discrimination index of more than 100% means that the animals spent more time exploring the novel object than the familiar one. Control animals spent significantly more time exploring the novel object than the familiar one (P < 0.05), whereas animals treated with MTX spent an equal amount of time investigating both objects (figure 5). There was no difference in average total exploration time for the acquisition and recollection phase for both groups, and there was also no difference in average total exploration time between the control animals and the animals treated with MTX (data not shown).

![Figure 5: Discrimination index in the novel object recognition task (n = 8 per group). The time spent exploring the novel object is expressed as percentage of the time spent exploring the familiar object (set as 100%) with the standard error of the mean. Control animals (□) spent more time exploring the novel object than the familiar one (P < 0.05), whereas animals treated with MTX (■, 250 mg/kg) spent an equal amount of time exploring both objects.](image)

**Discussion**

This study investigated the long-lasting effects of methotrexate (MTX) on hippocampal cell proliferation and cognitive behavior in rats. A distinct effect was seen on hippocampal cell proliferation in a dose-dependent manner three weeks after an intravenous injection of MTX. This was consistent with previous findings in our lab (unpublished data). Cytostatics, such as MTX, are designed to interfere with the process of cell division; therefore, the inhibition of hippocampal cell proliferation could be anticipated. The formation of new neurons out of stem cells in the dentate gyrus of hippocampus (neurogenesis) is thought to play an important role in learning and memory processes (Doetsch and Hen, 2005). Studies have shown that aging (Bizon and Gallagher, 2003), or stress (Gould et al, 2000) has a negative effect on neurogenesis and cognition, whereas an enriched environment (Kempermann, 2002), or running wheel activity (Persson et al, 2004) increases neurogenesis and cognitive performance.

In our study, the lowest dosage given to the animals (37.5 mg/kg) already resulted in a significant decrease in cell proliferation. This finding is of particular interest, since it is suggested that MTX does not pass the blood-brain barrier when administered in a dosage equivalent to the one used in the adjuvant regimen of chemotherapy for breast cancer (Boogerd, 1995). Our findings may indicate that even a low dosage is able to pass the blood-brain-barrier in rats, or that other factors play a role in the observed neurotoxicity in the current study. One of these factors may be the sickness that is observed in animals treated with MTX, although immunocytochemistry was performed after the animals recovered.
All dosages used in this study induced sickness approximately three days after treatment, which was expressed in a decrease in body weight gain, fluffy fur, bad general appearance, and mild diarrhea. The effects are similar to the clinic, where patients treated with MTX also suffer from body weight loss and diarrhea (Flombaum and Meyers, 1999). Previous physiological studies in our laboratory indicate that directly after treatment with MTX body temperature slightly increased (suggesting a mild fever) although this observation failed to reach significance (unpublished data). Whether sickness itself can have long-lasting effects on hippocampal cell proliferation will be explored in a future study.

Dietrich and colleagues examined the effect of carmustine (BCNU) and cisplatin (two other frequently used cytotoxic agents) on cultured brain cells and found that the agents were more toxic to progenitor cells of the CNS and non-dividing oligodendrocytes than for multiple cancer cell lines. The effect of these cytotoxic agents on cell death and cell division was also studied in mice. Three intraperitoneal injections of BCNU significantly increased cell death for up to ten days after treatment in the corpus callosum and the hippocampal dentate gyrus, and up to six weeks in the subventricular zone. Similar effects were seen after three intraperitoneal injections of cisplatin. BCNU also significantly decreased cell division up to six weeks after treatment in the subventricular zone, the corpus callosum, and in the hippocampal dentate gyrus. Cisplatin showed similar effects, but the number of dividing cells returned to normal levels in the subventricular zone and the dentate gyrus six weeks after treatment (Dietrich et al., 2006).

In breast cancer patients, CMF chemotherapy is associated with cognitive decline. This decline is mostly noticed 2-6 years after treatment (Kreukels et al., 2005; Schagen et al., 1999), but can be noticed as early as three months after CMF chemotherapy (Wieneke and Dienst, 1995). The decline is observed in a wide range of brain functions, including memory, concentration, and speed of information processing. Of the cytotoxic agents that are represented in the CMF regimen, MTX is thought to be the agent most responsible for this cognitive impairment (Kreukels et al., 2005). Since we showed that MTX induces a profound and long-lasting decline in hippocampal cell proliferation (which likely reflects an inhibition of the process of neurogenesis) we hypothesized that this decline in cell proliferation could also play a role in the cognitive impairment observed in cancer patients after CMF treatment. To test this hypothesis, we performed two hippocampal-dependent learning and memory tasks (MWM and the NOR task), after treatment with MTX. In a recent paper Ahles and Saykin reported that the most affected cognitive functions after treatment with chemotherapy are, amongst others, episodic, visual and spatial memory (Ahles and Saykin, 2007), which can be tested in a MWM and a NOR task.

In the MWM task, animals were trained to learn where a hidden platform was located allowing an escape from the water. Both control and treated animals learned the task adequately. However, the animals treated with MTX showed a longer latency time to cross the platform location in the probe trial, reflecting an impairment of spatial memory function. There was also a tendency for these animals to spend less time in the right quadrant compared to the control animals; however, this observation failed to reach significance (data not shown). In the NOR task, the animals treated with MTX failed to distinguish a novel object from a familiar one, indicating a decrease in the comparator function of the hippocampus. Cell proliferation in the olfactory bulb was also affected in the animals treated with MTX (data not shown), which could cause a change in the ability to smell and the ability to make a distinction between the different objects. Since the objects in our test were made of the same material and cleaned after each session, it was not possible for the animals to recognize an object by smell. The hippocampal dependency of NOR task can be debated, however, Forwood and colleagues describe that when a NOR is performed with spatial cues present, which was the case in our study, the task becomes more hippocampal-dependent (Forwood et al., 2005).

The impairment in hippocampal-dependent tasks is in line with a number of studies. Madhyastha and colleagues found a learning and memory impairment, but no anxiolytic effects in the two-compartment conditioned avoidance task after multiple intracerebroventricular injections of MTX in
Wistar rats (Madhyastha et al, 2002). Sieklucka-Dziuba and colleagues reported an impairment of long-term memory in the passive avoidance task fourteen days after a single dosage of MTX injected intraperitoneal in Albino Swiss mice (Sieklucka-Dziuba et al, 1998). Moreover, Yanovski and colleagues showed in Lewis-inbred rat pups impaired learning of environmental events in a conditioned emotional response task and conditioned taste aversion task after a single neonatal intraperitoneal MTX injection (Yanovski et al, 1989). Shors and colleagues treated male Sprague-Dawley rats with the anti-mitotic MAM for fourteen days and found a distinct decrease in BrdU positive cells in the dentate gyrus. This decrease, however, did not affect performance in the MWM or in the contextual fear conditioning, but did affect performance in the trace fear conditioning (Shors et al, 2002). Winocur and colleagues treated BALB/C mice with a combination of MTX and 5-fluorouracil. Drug-treated mice showed impaired learning in a MWM, in a non-matching-to-sample test (NMTS), and in a delayed-NMTS of non-spatial memory, compared to control animals (Winocur et al, 2006). Since the latter tests are not hippocampal dependent, it is possible that the hippocampus is not the only brain area responsible for the cognitive decline seen in patients after treatment with chemotherapy. Other brain areas might also be involved, for example the volume of grey and white matter as described by Inagaki and colleagues (Inagaki et al, 2007).

Not all literature points to a learning impairment after chemotherapy. Lee and colleagues found that female Fischer-344 rats treated with cyclophosphamide or 5-fluorouracil (both commonly used cytostatics) learned to find the location of a platform in the MWM task even faster than control animals seven weeks after recovery from the chemotherapy treatment; 29 weeks after the treatment, significant effects were no longer found between treated animals and controls (Lee et al, 2006). In that study, animals received five intraperitoneal injections every four weeks, for a total of eighteen weeks. The authors attribute the unexpected improvement of cognitive function to the fact that cytostatics lower estrogen production. Reduced plasma estradiol in rats is associated with improved learning in the MWM (Healy et al, 1999); this is supported by Bimonte-Nelson and colleagues (Bimonte-Nelson et al, 2004). In humans, chemotherapy may lead to premature menopause (Ganz, 2005; Van Dam et al, 1998), which reduces estrogen levels (Buckler, 2005). In contrast to rats, however, low estrogen levels in humans are associated with cognitive decline (Sherwin, 2000).

Not only chemotherapy is associated with cognitive decline. Other adjuvant treatments for cancer, such as radiation, are also associated with similar long-term effects. Raber and colleagues found that C57BL/6 mice showed hippocampal-dependent spatial learning and memory impairments in the Barnes maze, but not in the MWM task three months after localized radiation to the bilateral hippocampus and cortex (Raber et al, 2004). Rola and colleagues found a similar effect after whole brain radiation in C57BL/6 mice, but here a spatial memory retention deficit was seen in the MWM task (Rola et al, 2004). Comparable effects after radiation were seen in rats. For example, Madsen and colleagues found that Wister rats performed worse in an object recognition task, but performed well in the MWM task after multiple radiation treatments directed at the hippocampal area (Madsen et al, 2003). Yoneoka and colleagues showed that Fisher rats performed well in the MWM task and the passive avoidance task six and nine months after multiple treatments with fractioned whole brain radiation, but worse in the same task twelve months after treatment (Yoneoka et al, 1999).

In the current study the observed decline in cell proliferation seen in the animals after treatment with MTX might not be the main or sole explanation for the observed cognitive impairment seen in patients after treatment with chemotherapy. Ahles and Saykin describe several potential mechanisms for this cognitive impairment, which could also contribute to the decrease in cell proliferation; these mechanisms include DNA damage, oxidative stress, encephalopathy, cytokine activation, telomere length and telomerase activity, neurotransmitter activity, and neuronal repair (Ahles and Saykin, 2007).

We want to emphasize that in our study, MTX was used as an animal model for adjuvant chemotherapy given to breast cancer patients. However, this does not mean that all cytostatics will produce the same effects on cell proliferation or behavior. In order to validate our animal model, we
will test other cytostatics in a future study. Furthermore, it seems that the learning task and the time after treatment are crucial for finding a correlation between the decrease in hippocampal cell proliferation after cytostatics and the effect on cognitive behavior.

In conclusion, it can be said that MTX affects hippocampal cell proliferation in a dose-dependent fashion. This lasting decrease in hippocampal cell proliferation might be responsible for the negative effect seen in spatial and comparator memory after treatment with MTX.

It is expected that in 2015 the incidence of breast cancer will be around 17,000 in the Netherlands alone (Signaleringsrapport Kanker in Nederland, 2004), and that in half of these patients chemotherapy will be part of the treatment strategy. Therefore, it is important to systematically investigate the underlying mechanisms of any potential late effect of chemotherapy that can seriously affect the quality of life of these patients. This may help elucidate the mechanisms that underlie the cognitive deficits found in a number of breast cancer patients treated with adjuvant chemotherapy.

Acknowledgments

These studies were supported by a grant from Netherlands Cancer Institute/Antoni van Leeuwenhoek Hospital, and from the Gratama Foundation.
