ABSTRACT — In this chapter we use neutral hydrogen (H\textsubscript{I}) and optical spectroscopic observations to compare the timescales of a merger event, starburst episode and radio-AGN activity in the radio galaxy B2 0648+27. The methods used in this chapter are illustrative of our approach for studying a larger sample of nearby radio galaxies in the following chapters. We detect a large ring-like structure of H\textsubscript{I} in emission around the early-type host galaxy of B2 0648+27 ($M_{\text{HI}} = 8.5 \times 10^{9} M_{\odot}$, diameter = 190 kpc). Together with the presence of very faint optical tails in this system, we interpret this as the result of a major merger that occurred $\gtrsim 1.5$ Gyr ago. From modelling optical long-slit spectra we find that a young stellar population of $0.3$ Gyr, indicative of a past starburst event, dominates the stellar light throughout the galaxy. The off-set in time between the merger event and the starburst activity in B2 0648+27 suggests that the starburst was triggered in an advanced stage of the merger, which can be explained if the gas-rich progenitor galaxies contained a bulge. Although the exact age of the radio source remains uncertain, there appears to be a significant time-delay between the merger/starburst event and the current episode of radio-AGN activity. We also observe an outflow of emission-line gas in this system, which is likely related to superwinds driven by the stars that formed during the starburst event. We argue that the radio galaxy B2 0648+27 is a link in the evolutionary sequence between Ultra-Luminous Infrared Galaxies (ULIRGs) and genuine early-type galaxies.

Published as:
2.1 Introduction

Merger events are often invoked as the trigger of the activity in galaxies. Extreme examples are major merger systems such as Ultra-Luminous Infra-Red Galaxies (ULIRGs), which owe their extreme infra-red colours to a massive starburst, often in combination with a dust-enshrouded AGN. In the hierarchical model of galaxy formation, early-type galaxies such as E and S0 galaxies form the end products of merging systems. The overwhelming majority of bright, low-z radio sources are hosted by these early-type galaxies, which often still show optical signatures of the merger event (such as optical tails, bridges, shells; Smith & Heckman 1989). In addition, a growing number of radio galaxies is found to contain a young or intermediate age stellar population, indicating that they are post-starburst systems (e.g. Aretxaga et al. 2001; Wills et al. 2002, 2004; Tadhunter et al. 2002, 2005; Raimann et al. 2005; González Delgado et al. 2006). The same holds for optically selected AGN from the Sloan Digital Sky Survey (SDSS), of which a significant fraction experienced bursts of star formation in the recent past (Kauffmann et al. 2003).

A connection between mergers and galactic scale starburst events has been well established and modelled (e.g. Barnes & Hernquist 1991; Barnes & Hernquist 1996; Mihos & Hernquist 1994, 1996; Springel et al. 2005a; Kapferer et al. 2005). Although the models of Springel et al. (2005a) and Kapferer et al. (2005) predict a connection also between mergers and AGN activity, observationally there remain considerable uncertainties about this, and in particular about the timing of the events. While some studies do find trends between merger/interaction events and AGN activity (e.g. Canalizo & Stockton 2001; Wu et al. 1998; Heckman et al. 1986), others find no such trends (e.g. Grogin et al. 2005; Dunlop et al. 2003; Lutz et al. 1998). To investigate this further it is worth looking at the “order-of-events” in individual nearby galaxies that show signs of both merger and starburst activity as well as AGN activity.

An excellent object to do this in detail is the nearby (z = 0.0412)\(^*\) radio galaxy B2 0648+27.\(^*\) This galaxy contains a compact radio AGN (log \(P_{1.4\text{GHz}}\) = 23.7 W Hz\(^{-1}\)). The early-type host galaxy has an elliptical morphology, but deep optical colour images reveal a low surface brightness envelope and faint plume- or tail-like structures (Heisler & Vader 1994). The HST image from Capetti et al. (2000) shows a patchy distribution of dust, as well as what appear to be regions of star formation. Morganti et al. (2003, hereafter Paper I) found a ring-like structure of H\(_I\) gas that surrounds the host-galaxy, suggesting a major merger happened in this system. In this chapter we present the results from new H\(_I\) data (Sect. 2.3) as well as a stellar population analysis from new optical spectra (Sect. 2.4). We use these to study the timescales between the merger event, starburst activity and onset of radio-AGN activity in B2 0648+27 and to determine the evolutionary stage of this galaxy.

2.2 Observations

We obtained 3 \(\times\) 12 hours of Westerbork Synthesis Radio Telescope (WSRT) data on 12 and 15 August 2002 using the 20 MHz band, 512 channels set-up, and on 28 December 2002 using 1024 channels over the 20 MHz band. The data have been reduced using the MIRIAD software. A data cube was constructed using a robust-Briggs’ weighting equal to 1 (Briggs

\(^*\)\(H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}\) used throughout this chapter. This puts B2 0648+27 at a distance of 174 Mpc and 1 arcsec = 0.84 kpc.

\(^*\)In this thesis we use the name B2 0648+27 for both the radio source as well as the galaxy that hosts the source.
Neutral hydrogen: the merger event

Figure 2.1 (left) shows a total intensity H\textsc{i} map of our new data. The H\textsc{i} gas forms a ring-like structure with a total mass of $8.5 \times 10^9 M_\odot$ and diameter of 190 kpc. Given the deeper observations it is not surprising that this mass is somewhat higher than the mass detected in Paper I (for our used value of $H_0$). The H\textsc{i} structure is asymmetric. The highest concentration of H\textsc{i} gas is found in the eastern part of the structure, with a surface density of $1.7 M_\odot$ pc$^{-2}$. The surface density threshold to trigger star formation in disk galaxies is predicted to be higher by a factor of a few (e.g. Martin & Kennicutt 2001), therefore the overall surface density of the H\textsc{i} in B2 0648+27 will be too low for large-scale star formation to occur. As a result, most of the H\textsc{i} may stay around for a very long time.

The PV-diagram in Fig. 2.1 (middle right) shows that the H\textsc{i} ring is not yet fully settled. The systemic velocity of B2 0648+27 ($12 \pm 4$ km s$^{-1}$, as we will derive in Sect. 2.5 from optical emission-lines), coincides with the velocity of H\textsc{i} detected in absorption (see below). Within the error it also agrees with the central velocity of the H\textsc{i} emission structure when we take into account the full range in velocity covered by the H\textsc{i}. This includes H\textsc{i} emission detected out to a velocity of about $v = 12.540$ km s$^{-1}$, which is located in the inner region, just south-west of the optical host galaxy (Fig. 2.1 - top right). The extended H\textsc{i}-gas

Figure 2.1: Left: Total intensity H\textsc{i}-emission map (contours) constructed from our robust +1 weighted data cube of B2 0648+27 and a nearby gas-rich companion to the north (J0651+2734 - see Sect. 2.3.1) overlaid onto an optical DSS image (grey-scale). Contour levels are 0.22, 0.36, 0.52, 0.71, 1.2, 1.5, 1.8, 2.1 \times 10^{20} \text{cm}^{-2}. Right (middle): Position-Velocity (PV) plot of the H\textsc{i} in the ring-like structure taken along the solid line in the left plot. Contour levels are in grey -0.25, -0.40, -0.55 and in black 0.32, 0.48, 0.68, 0.90, 1.15, 1.45 mJy beam$^{-1}$. Right (top): total intensity map of the H\textsc{i} emission gas with velocity $v > 12,500 \text{ km s}^{-1}$ (contours: 1.4, 2.4, 2.7 \times 10^{19} \text{ cm}^{-2}) overlaid on an optical DSS image (grey-scale). Right (bottom): H\textsc{i} absorption profile (uniform weighting) against the central unresolved radio continuum. The systemic velocity traced by optical emission-lines (see Sect. 2.5) is also plotted.
on the south-western side has a velocity closer to $v_{sys}$ than the extended H I in the north-east. This complex distribution of the H I indicates that the H I is still in the process of settling into a regular rotating ring. We argue that the H I gas in the inner region (with $v > 12500$ km s$^{-1}$) is part of the large-scale H I structure, with H I gas stretching from the optical host galaxy and curling around the system. This explanation would agree with faint optical tails found by Heisler & Vader (1994) in the inner part of the system.

The total amount of H I in and around the host galaxy of B2 0648+27 is unusually large for an early-type galaxy. It is comparable to a few times the H I content of the Milky Way. The large mass as well as the extended distribution of the H I structure around B2 0648+27 suggests that it formed during a major merger event, which included at least one (and possibly two) gas-rich galaxies (more details of this merger event are discussed in Sect. 2.7). A major merger event between gas-rich disk-galaxies can create large tails of H I (e.g. Hibbard & Mihos 1995; Hibbard & van Gorkom 1996; Hibbard et al. 2001). The gas in these tails can, if the environment is not too hostile, fall back onto the host galaxy and form a disk- or ring-like structure (Barnes 2002). The H I gas will need a few galactic orbits time to fully settle. Apparently, B2 0648+27 is in the evolutionary stage where tidal H I gas is falling back towards the host galaxy, but has not yet had time to settle into a regular rotating ring.

To get a lower limit for the age of the merger event we assume that the gas needed at least half an orbit to fall back into the observed morphology. Assuming (from Fig. 2.1) an orbital radius of 95 kpc and velocity of the gas of 200 km s$^{-1}$, we estimate that the first encounter between the merging galaxies was at least 1.5 Gyr ago. This age of the merger event is in agreement with the simulations of Barnes (2002), in which expelled gas during a merger event needs a similar timescale to fall back onto the galaxy. It also provides enough time for the host galaxy to gain the optical morphology of a genuine early-type galaxy (e.g. Hibbard & van Gorkom 1996).

As already discussed in Paper I, in the central region of B2 0648+27 we detect H I in absorption against the unresolved compact radio source (Fig. 2.1 bottom right). From a continuum image (see Fig. 3.1), constructed using the line-free channels in our data, we derive a continuum flux of about 156 mJy beam$^{-1}$, the same as Fanti et al. (1987) found in VLA data at 1.4 GHz. The absorption in our uniform weighted data has a peak of about -1.15 mJy beam$^{-1}$ and a FWHM of about 210 km s$^{-1}$. We note, however, that part of the absorption line could be filled-in with H I emission that is in the same beam. The resulting optical depth is about 0.74% and the corresponding column density $N_{HI} \sim 2.8 \times 10^{20}$ cm$^{-2}$ (assuming $T_{spin} = 100$K).

2.3.1 H I companions

We detect in H I a total of 17 galaxies in the field of B2 0648+27. Of these, 10 have not previously been catalogued.§ Figure 2.2 shows the spatial distribution of the H I-detected galaxies. All but one of these H I-detected galaxies also have a faint optical counterpart that is visible in the DSS image of this region (the only H I-detection for which an optical counterpart is not obvious is #16). Table 2.1 gives a full list of the H I-detected galaxies. In order to facilitate comparing the radial velocities of these galaxies, the galaxies are listed and numbered according to their velocity relative to B2 0648+27 ($\Delta v$).

It is notable that, although the region is H I rich, B2 0648+27 appears to lie not in the

---

§Based on results from the NASA/IPAC Extragalactic Database (NED).
Table 2.1: HI rich galaxies in the field of B2 0648+27. Col. 1 gives the number assigned to the galaxy (see also Fig. 2.2) - ordering is in accordance with increasing $\Delta v$. Col. 2 gives the name. In case the galaxy has not been previously catalogued, the name is in accordance with the nomenclature of some of the companions from Paper I; in case the galaxy has been previously catalogued the reference is given in Col. 3. The next columns give the R.A. and Dec of the galaxy, the distance to B2 0648+27, the velocity, the velocity difference w.r.t. B2 0648+27 and the total H\textsc{i} mass (corrected for the primary beam of the WSRT).

Figure 2.2: H I-detected galaxies in the field of B2 0648+27. The observations were centred on B2 0648+27. This total intensity map is different from the one of Fig. 2.1 in the sense that it has been constructed by adding all the signal above $5\sigma$ in at least two consecutive channels in our robust +1 weighted line-data cube. Numbers are given in order of $\Delta \nu$ and correspond to numbers in Table 2.1. Contour levels are: $0.33, 0.58, 0.83, 1.1, 1.3, 1.6, 1.8, 2.3, 2.8, 3.3, 3.8, 4.3, 4.8 \times 10^{20} \text{ cm}^{-2}$ (the zoom-in of B2 0648+27 has as lowest contours $0.17, 0.38 \times 10^{20} \text{ cm}^{-2}$ to illustrate more clearly the ring-like structure).
centre, but towards the outskirt of this ensemble of H\textsc{i}-detected galaxies. Most of these galaxies lie east and south of B2 0648+27, and most systems have a radial velocity that is lower than that of B2 0648+27. The fact that no X-ray source has been detected near B2 0648+27 in the ROSAT X-Ray All-Sky Survey also suggests that B2 0648+27 is not located in the central region of a rich cluster. We can, therefore, conclude that B2 0648+27 is located in a field environment with gas-rich galaxies that are mostly situated relatively far away.

The companion J0651+2734 (#4) is a relatively nearby companion, both in radial velocity and spatial distance. The total H\textsc{i} mass of J0651+2734 is $M_{\text{H}\textsc{i}} = 8 \times 10^8 M_\odot$. J0651+2734 appears to show a faint extension of H\textsc{i} gas towards B2 0648+27 (visible in Fig. 2.1), but additional data are necessary to confirm this.

### 2.4 Optical spectra: the starburst event

Optical spectra of B2 0648+27 are extracted at three places along the slit, which was aligned along the major axis of the host galaxy. The locations are on the nucleus and in regions 3.2 arcsec (2.7 kpc) NE and SW of the nucleus, with an aperture of 2.8 arcsec for each region. Figure 2.3 shows the spectrum of B2 0648+27 in the nuclear and NE region. The spectra look remarkably similar in the different regions (the spectrum in the SW region looks almost identical to the NE-spectrum).

Despite the fact that B2 0648+27 is an early-type galaxy, the spectra display strong Balmer absorption lines and an UV-excess shortward of the 4000Å-break. The strong Balmer absorption lines and Balmer break are characteristic of a dominant contribution from a young or intermediate age stellar population (it is unlikely that the AGN-component has a large contribution to the UV-excess, as we will discuss in Sect. 2.4.1).

In order to study in detail the stellar populations in the host galaxy of B2 0648+27, we model the continuum spectral energy distribution (SED) of the optical spectra in the three
regions, taking into account both stellar and AGN-related continuum components (see also Tadhunter et al. 2002, 2005; Wills et al. 2002, 2004). This is preferred above using absorption line indices at face-value, because most of the age sensitive diagnostic absorption lines are affected by emission-line contamination (an exception is Ca II K). Subsequently, we will make a more detailed comparison between the data and the models by investigating in detail the age sensitive Ca II K and Balmer absorption lines in order to constrain our result even better.

### 2.4.1 Continuum modelling

For the modelling of the spectra of B2 0648+27, stellar population models of Bruzual & Charlot (2003) are used. These are based on Salpeter IMF and solar metallicity, instantaneous starbursts. Figure 2.4 clarifies the procedure used. We use a $\chi^2$ minimisation technique to fit combinations of a 12.5 Gyr old stellar population (OSP) and a young stellar population (YSP) to the observed spectrum. YSP template spectra with a range in age from 0.01 to 9 Gyr are used for this. We compare the total flux of the combined OSP and YSP model spectrum with the observed flux in wavelength-bins along the spectrum. A normalising bin was chosen in the wavelength range 4720 - 4820 Å. We are not able to a priori determine the reddening using Hα/Hβ in the host galaxy of B2 0648+27, because the Hβ absorption due to a YSP appears to be significant in this system, which dilutes the Hβ emission line. Apart from Hα, the other Balmer lines are too weak to be used. In the modelling this is dealt with by leaving the reddening as a free parameter in the YSP template spectra. The Seaton (1979) reddening law was used to redden the YSP template spectra. For the $\chi^2$ fitting we assume an error of $\pm 6\%$ in each wavelength bin, in agreement with the uncertainty in the flux calibration. Note that, since the flux calibration errors are not likely to be independent between the various
wavelength bins, we can merely use the reduced $\chi^2$ values as an indication of the region of parameter space for which the modelling provides good results, rather than derive accurate statistical properties of the fitting procedure itself. For that we also need to inspect the model-fit to our spectra visually.

In the region shortward of 4000 Å the spectrum could be diluted by UV-excess due to nebular continuum (see e.g. Dickson et al. 1995, and references therein) and AGN related effects (see discussion in Tadhunter et al. 2002). To investigate the role of the AGN, we also model the spectra including a power-law component. To correct for the nebular continuum, we use the Starlink software FIGARO to generate a nebular continuum, comprising the blended higher Balmer series (>H8) together with a theoretical nebular continuum (a combination of free-free emission, free-bound recombination and two-photon continua), which we subtract from the observed spectra. For normalisation we use the observed H\textalpha emission-line. The H\textalpha emission-line in our nuclear spectrum is best fitted with a two-component Gaussian line-profile (see also Sect. 2.5). Therefore separate nebular continua are generated with the same redshift and line width as the two components. Because we do not a priori know the reddening in the host galaxy of B2 0648+27, we consider different cases of attenuation of this nebular continuum. We note that the most extreme cases - maximum nebular continuum subtraction (i.e. no attenuation applied) and no nebular continuum subtraction (i.e. assuming very large attenuation) - do not significantly alter our main results.

Nuclear region

Figure 2.4 shows the best fit to the overall spectrum in the nuclear region. This best fit consists of a two-population fit of both a 12.5 Gyr OSP and a 0.3 Gyr YSP with reddening $E(B - V) = 0.3$ (see also Table 2.2). In Fig. 2.5 the $\chi^2$ results are given for the fitting procedure across the whole range of parameters for age and reddening of the YSP. It is clear that the lowest $\chi^2$ results nicely converge around age = 0.3 Gyr and $E(B - V) = 0.3$. However, on the basis of the SED modelling alone we cannot rule out any results for which $\chi^2 < 1$. Model-fits for which $\chi^2 > 1$ systematically contain residuals larger than 6\% across several wavelength bins (i.e. larger than our flux calibration errors), and therefore we can rule out this range of model parameters.

To further refine the stellar population properties we visually inspect the different model-fits in the region around the 4000 Å break, where the important age-indicator Ca II K (e.g. Tadhunter et al. 2005) and the age-sensitive Balmer lines (e.g. González Delgado et al. 1999) are also located. Although the Balmer lines are likely contaminated by emission-line infilling, Ca II K should be a relatively 'clean' age-indicator. The zoom-in of Fig. 2.6 shows our best $\chi^2$-fit model, with age = 0.3 Gyr and $E(B - V) = 0.3$ for the YSP. Despite the fact that the fit is not perfect (due to inaccuracy in the flux-calibration and emission-line contamination in the cores of the Balmer lines), this model nevertheless provides a good fit to the Ca II K, Balmer and G-band features. We visually inspected the line fitting in the region around the 4000 Å break also for the other model templates for which $\chi^2 < 1$. Although some of these fits are also satisfactory (given the uncertainties in our used method - see Sect. 2.4.3), the fit degrades quickly for increasing $\chi^2$ results. Based on these results we argue that it is sufficient to model the spectrum of the nuclear region with a single post-starburst YSP of age 0.3\pm0.1 Gyr and reddening $E(B - V) = 0.3 \pm 0.1$ superimposed onto a 12.5 Gyr OSP. Figure 2.5 and Table 2.2 show that in the nuclear region this post-starburst stellar population contributes about 82\% of the visible light in the slit, corresponding to about 25\% of the total stellar mass.
**Figure 2.5:** $\chi^2$ results (left) and % of the starlight coming from the YSP (right) across the whole range of parameters for age and reddening of the YSP in the nuclear region. Contour levels are: 'reduced $\chi^2$': 0.45, 0.6, 1.0, 2.0, 4.0, 7.0, 10.0, 15.0, 20.0; 'reduced $\chi^2$ (zoom)': 0.45, 0.5, 0.6, 0.7, 0.8, 1.0, 1.5, 2.0, 5.0, 10.0; 'YSP flux %': 10, 30, 50, 60, 70, 80, 90, 100; 'YSP flux % (zoom)': 40, 50, 60, 70, 80, 90, 100.

**Figure 2.6:** Zoom-in of figure 2.4; detailed fits to the nuclear spectrum in the region of the age sensitive Ca II K and Balmer lines. The dotted line is the observed spectrum, the solid line represents the best fit model (12.5 Gyr OSP + 0.3 Gyr YSP with $E(B-V) = 0.3$). The reason that the fit is not perfect is mainly due to flux-calibration errors and emission-line contamination in the Balmer lines.
Figure 2.7: $\chi^2$ results of in the NE (left) and SW (right) aperture across the whole range of parameters for age and reddening of the YSP. Contour levels for both NE and SW aperture are: 'reduced $\chi^2$': 0.4, 0.6, 1.0, 2.0, 4.0, 7.0, 10.0, 15.0, 20; 'reduced $\chi^2$ (zoom)': 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.2, 2.0, 5.0, 10.0.

Figure 2.8: Detailed fits to the off-nuclear spectra in the region of the age sensitive Ca II K and Balmer lines. The dotted line is the observed spectrum, the solid line represents the best fit model (12.5 Gyr OSP + 0.4 Gyr YSP with $E(B-V) = 0$).
Table 2.2: Properties of the YSP for the different spectra. The values are obtained from the normalising bin in our SED modelling (4720-4820 Å).

Off-nuclear regions

We also fit the Spectral Energy Distribution in the apertures NE and SW of the nucleus. We assume that the nebular continuum is not significant in the analysis of these off-nuclear regions. Here the emission lines are much weaker than in the nuclear region, where the nebular continuum subtraction did not significantly affect our results anyway.

Results of the model-fitting in the off-nuclear regions are given in Table 2.2. In both the NE and the SW region, the best fit consists of a combination of the 12.5 Gyr OSP and a YSP of age between 0.3 and 0.4 Gyr with E(B−V) = 0. Figure 2.7 shows that for the off-nuclear regions the χ² results converge to this unique solution. For similar reasons as for the nuclear region, we can discard any fit for which χ² > 1.

From visual inspection of the region around the 4000 Å break and the age-sensitive Ca II K and Balmer lines (Fig. 2.8) we conclude that the fits in the range age = 0.4^{+0.2}_{−0.1} with E(B−V) = 0^{+0.1} give satisfactory results, and that we can safely discard any models outside this range. Therefore, within the uncertainty of the SED modelling, the YSP in the off-nuclear regions has an age similar to that of the YSP in nuclear region. Table 2.2 shows that the young, post-starburst stellar population contributes to a significant fraction of the total stellar light and mass also in the off-nuclear regions. Reddening of the YSP is much more pronounced in the nuclear region than in the off-nuclear regions. However, we can not make a general statement about the reddening in B2 0648+27 based on these three regions alone, since Capetti et al. (2000) observed the dust distribution in B2 0648+27 to be patchy.

Effect of power-law component

Since B2 0648+27 has an active nucleus, we also tried to fit the nuclear spectrum with a power-law component (with varying slope) in addition to the fit of the old + (reddened) young stellar populations. The optical AGN in B2 0648+27 is not likely to be very strong, at least not in the direct light, since no optical point-source was detected in the HST image of Capetti et al. (2000). Scattered quasar light is likely correlated with the strength of the emission lines (Tadhunter et al. 2002), and in that sense in particular the off-nuclear regions make clear that this cannot be a major contribution either.

When we include a weak power-law component in our SED modelling, this does not provide significantly better results. We therefore do not expect that light from the AGN has a major impact on our results.
**Table 2.3:** Absolute mass of the old and young stellar population in the various regions.

### 2.4.2 Stellar masses

Table 2.3 gives the absolute mass of the OSP and YSP in the three regions that we investigated. The masses are calculated from the flux of the YSP and OSP at 4770 Å (the central $\lambda$ of our normalising bin; see also Table 2.2). The YSP and OSP flux (taking into account reddening effects from Table 2.2) are scaled to stellar masses using the template spectra of Bruzual & Charlot (2003). The uncertainty in the stellar mass estimates is based on uncertainties from the SED modelling (Table 2.2).

Because there is an additional uncertainty of a factor of 2 in the stellar mass estimates in the various regions (due to slit-losses during the observations; Sect. 2.2) and because these regions occupy only a small area of the entire galaxy (2.6 kpc$^2$ each), we also estimate the total stellar mass in the galaxy using the photometric B-band magnitude of B2 0648+27 ($m_B = 13.98$; de Vaucouleurs et al. 1991). We use our results from Table 2.2 and the spectral synthesis results of Charlot et al. (1996) to make the total mass estimates in Table 2.3, although we note that our mass estimate is based on the derived values of the stellar populations in three small regions and that the stellar population parameters could be different at other locations.

As can be seen from Table 2.3, the mass of young stars in B2 0648+27 is high for a galaxy that has been classified as early-type. The starburst event that formed these young stars 0.3 Gyr ago has most likely been the result of a major merger (e.g. Mihos & Hernquist 1994, 1996; Springel et al. 2005a), which is in agreement with our H I study. Apparently there is a significant time-delay between the initial encounter (as dated by the H I analysis) and the onset of the starburst event. We will discuss this in more detail in Sect. 2.7.

### 2.4.3 Uncertainties in our method

Of course there is a degree of uncertainty introduced by observational errors (such as flux calibration) and by the assumed parameters of the synthesis models that we used in our fitting procedure (duration of the starburst, the assumed Salpeter IMF and metallicity).

Uncertainties in the flux calibration could be the reason that in particular in the red part of the spectrum the fit is not perfect. However, we do not expect that this will significantly change our results, since our visual inspection of the detailed fits in the blue part of the spectrum (around 4000 Å) is in excellent agreement with the reduced $\chi^2$ results.

For a detailed discussion of the uncertainties in the assumed parameters of the synthesis models we refer to Tadhunter et al. (2002). As discussed in Tadhunter et al., the major uncertainty in these model parameters is the assumed shape of the IMF. This may lead to
2.5 Emission-line gas

Emission lines of ionised gas are seen out to a radius of about 5 kpc (6 arcsec) from the nucleus. The fit of the \([\text{O III}]_{\lambda 4959/\lambda 5007}\) doublet line requires two Gaussian components (a “narrow” and a “broad” one) in the central region (Fig. 2.9). In Fig. 2.10 we trace the kinematics of these two components. Figure 2.10A shows that the broad component is detected out to about 2.5 kpc on either side of the nucleus (beyond that the noise gets too high to reliably fit a broad component). The broad component is therefore clearly resolved. The

\centering
\includegraphics[width=0.5\textwidth]{figure29.png}
\caption{[O III]$_{\lambda 4959/\lambda 5007}$ in the central region (aperture 1.2 arcsec). The profile is fitted by two doublet-components.}
\end{figure}

uncertainties of a factor 2-3 in the total mass estimates in Table 2.3 (on top of the factor of 2 due to observational inaccuracies; Sect. 2.2). We do not expect significant sub- or super-solar abundances, since the progenitor systems were most likely gas-rich disk galaxies. Moreover, Sarzi et al. (2005) recently investigated the effect of metallicity on a SED fitting technique for the bulge-regions of nearby galaxies. They conclude that substituting the solar for 2.5 $\times$ solar metallicity YSP template spectra does not change the results for age and light percentage of the YSP dramatically. The most significant effect is that super-solar metallicities can mimic additional reddening, in which case our solar-abundance models might overestimate the derived $E(B-V)$. Finally, following Tadhunter et al. (2002), the predicted age of the YSP should at least be a firm lower limit of the age of the starburst event, also if the star formation occurred over a certain period instead of an instantaneous burst. We would like to note that our modelling technique (consisting of a combination of an old plus a single young stellar population) is insensitive to multiple bursts of star formation. Nevertheless, from the excellent fit that we obtain to the spectra of B2 0648+27, we argue that any contribution from periods of star formation other than the one that occurred 0.3 Gyr ago is likely to be only minor. In particular, the light contribution of a very recent starburst (<0.3 Gyr ago) would be relatively strong. We can therefore safely conclude that the most recent period of intense star formation in B2 0648+27 was 0.3 Gyr ago, although more subtle bursts or periods of star formation (in particular much longer ago) cannot be ruled out completely with our used method.
rotation pattern of the narrow and broad component are very similar and the broad component is blueshifted with a fairly constant velocity shift of about 300 km s$^{-1}$ w.r.t. the narrow component (Fig. 2.10B). The FWHM of the broad component reaches about 1400 km s$^{-1}$ at the nucleus (Fig. 2.10C). It is difficult to explain such a velocity dispersion by gravitational motion of the ionised gas. We therefore argue that the narrow component emission-line gas traces the rotational pattern of the galaxy and the broad component most likely represents an outflow of ionised gas from the host galaxy of B2 0648+27.

We estimate the systemic velocity of B2 0648+27 to be $v_{\text{sys}} = 12345 \pm 46$ km s$^{-1}$, which is the centre of the position-velocity curve of the narrow component gas. The error in $v_{\text{sys}}$ consist of uncertainties in the $\lambda$-calibration and in determining the central velocity of the position-velocity curve. Within the errors, our derived value for $v_{\text{sys}}$ is in agreement with previous optical measurements. The rotation of the narrow component emission-line gas is...
in the same direction as the large-scale H\(^1\) structure, although the optical emission-line gas is only detected within the central beam of our H\(^1\) observations.

The outflowing gas is blueshifted and therefore moving towards us. Given the fact that the radio source is compact and the optical AGN quite weak, we argue that the current AGN-activity alone can not be responsible for the observed outflow. A likely driving mechanism for the outflow of ionised gas is a starburst driven superwind (e.g. Heckman et al. 1990), produced by the YSP in B2 0648+27. In that case substantial dust-obscuration is necessary to explain why we do not detect a redshifted wing to the emission-line profile as a result of outflowing gas on the opposite side of the galaxy. Although the reddening that we find from our SED modelling (both in the nuclear and in the off-nuclear regions) is probably not enough to explain such an obscuration, more dust might still be located deep inside the galaxy along our line-of-sight, which is difficult to trace with our SED modelling technique if the detected starlight is dominated by an overlaying YSP that is not that heavily obscured.

2.6 Radio continuum: the radio-AGN activity

A detailed study of the radio source B2 0648+27 has been done by Giroletti et al. (2005a). B2 0648+27 is a compact radio source, about 1 kpc in size, with a double lobed structure at sub-arcsec scale, as already observed at 8 GHz in Paper I. From an estimate of the radio spectral break frequency from total flux density measurements, Giroletti et al. (2005a) estimate that the minimum age of this radio source is \(9.9 \times 10^5\) years.

This does not rule out the possibility that there have been previous periods of radio-AGN activity. Also, Blundell & Rawlings (2000) have argued that spectral break frequency measurements may not always reflect the true age of radio sources, because of erroneous approximation of the magnetic field strength and continuous replenishment of energetic electrons. In this respect, the most extended double radio sources may be much older (0.1 - 1 Gyr) than predicted by traditional spectral ageing arguments. However, for compact radio sources with lifetimes much shorter than the observable radiative lifetimes of synchrotron-emitting particles (few \(\times 10^7\) yr), spectral age estimates should be much more reliable and comparable to ages estimated from advance speeds of the radio plasma.

Based on advance speeds, studies by e.g. Gugliucci et al. (2005) show that the typical age of Compact Symmetric Objects (CSOs) is at most a few thousand years. Of course we have to be careful to compare B2 0648+27 with these CSO sources, because, according to Giroletti et al. (2005a), B2 0648+27 is a Low Power Compact (LPC) with non-relativistic jets.

Nevertheless, despite the uncertainty in the exact age of the radio source, it is likely that at least the current phase of radio-AGN activity in B2 0648+27 started long after the merger/starburst event.

2.7 Discussion

In the recent history of the nearby radio galaxy B2 0648+27 we distinguish three periods of enhanced activity:

- Major merger: \(\gtrsim 1.5\) Gyr ago → H\(^1\)
- Starburst event: \(\sim 0.3\) Gyr ago → optical spectra
- Radio-AGN activity: \(\gtrsim 0.001\) Gyr ago → radio continuum
The question arises to what extent these events are related. First we examine the relation between the merger event and the starburst episode, which has been well modelled by, for example, Mihos & Hernquist (1994, 1996). Their simulations show that the structure of the merging galaxies, more so than the orbital geometry, determines the nature of the starburst event. In an encounter between pure disk galaxies a prominent bar is formed during the first passage, which drives a rapid inflow of gas into the central region. The resulting high gas densities trigger a starburst, which dies out even before the galaxies finally merge. If the progenitor galaxies contain a bulge, they do not form a bar during their first encounter. Only when the galaxies finally merge, \( > 1 \text{ Gyr} \) after the first encounter, a powerful starburst is triggered. The case of B2 0648+27, which is an advanced merger that late in its lifetime experienced a starburst event, can be explained if the progenitor galaxies contained a bulge.

The current period of radio-AGN activity apparently followed \textit{long after} the starburst episode. The merger-simulations of Springel et al. (2005a), that also include black-hole (BH) accretion and feedback, suggest that the AGN is likely obscured during the initial stage of the starburst. It only becomes visible at a later stage, when delayed AGN feedback mechanisms remove dense layers of gas around it. Although B2 0648+27 could be confined for a certain amount of time (as suggested by Giroletti et al. 2005a), the apparent time-lag between the starburst episode and current period of radio-AGN activity is nevertheless large, and it is not at all evident that this can be explained by the models of Springel et al. (2005a).

So what could explain the apparent delay between the merger/starburst event and the triggering of the current phase of radio-AGN activity? Beside the fact that mergers are a good way of depositing gas in the central regions of radio galaxies (e.g. Barnes & Hernquist 1991; Barnes & Hernquist 1996; Barnes 2002), it might take a significant amount of time - and processes that are not yet well understood - to remove enough angular momentum of the gas so that it can be transported down to the sub-pc region of the central BH. Alternatively, the onset of the radio-AGN activity could be related to properties of the central engine itself, such as the required timescale for the coalescence of individual BHs in merging galaxies (e.g. Escala et al. 2004; Milosavljevic & Merrit 2001; Wilson & Colbert 1995).

It is worth to point out that there are other examples of radio galaxies in which a significant time-delay was found between a starburst event and the onset of the radio-AGN activity (Tadhunter et al. 2005). Also, based on CO results in radio galaxies, a substantial delay between the start of the merger event and the triggering of the radio jets has been proposed by Evans et al. (1999a,b). In addition to this, in Chapter 3, we presented \( \text{H} \text{I} \) results on a complete sample of nearby radio galaxies. There we discuss several other examples of compact radio sources that contain large-scale \( \text{H} \text{I} \) structures, possibly as a result of a major merger event that happened more than a Gyr ago. If a merger origin is confirmed, then also for these sources there is a large time-delay between the merger and the current phase of radio-AGN activity.

2.7.1 The “missing link”

Finally, we address the question to what extent B2 0648+27 is related to on the one hand systems in major merger, like Ultra Luminous Infra-Red Galaxies (ULIRGs) and on the other hand normal ellipticals. In Paper I already an evolutionary sequence was presented, in which B2 0648+27 is a proposed link between both classes of objects. From our new data, the timescales that we derive for the merger and starburst event in B2 0648+27 are in agreement with this evolutionary scenario.
Table 2.4: Bolometric luminosity of the nuclear YSP (across \( \lambda \)-range \( 0 - 30,000 \) Å), the total luminosity of this nuclear YSP absorbed by the dust (assuming \( E(B - V) = 0.3 \)), and the observed total far-IR luminosity of B2 0648+27.

\[
\begin{array}{ccc}
L_{\text{bol}} \ YSP & L_{\text{absorbed}} & L_{\text{FIR}} \\
(L_\odot) & (L_\odot) & (L_\odot) \\
\text{Nucleus} & (0.8 - 2.8) \times 10^{10} & (0.5 - 1.9) \times 10^{10} & 1.9 \times 10^{11}
\end{array}
\]

Figure 2.11: The evolution with age of \( L_{\text{bol}} \) of the YSP in the nuclear region, based on the used template spectra. The minimum and maximum luminosity curves are shown (based on Table 2.4). We also plot the limiting luminosities for Luminous Infra-Red Galaxies (LIRG) and Ultra Luminous Infra-Red Galaxies (ULIRG) (see Sanders & Mirabel 1996) in case \( L_{\text{bol}} \) would be entirely re-radiated in the far-IR.

B2 0648+27 also has a relatively high far IR-luminosity (\( L_{\text{FIR}} \sim 1.9 \times 10^{11} L_\odot \); Mazzarella et al. 1993). Could this FIR-luminosity be due to re-radiated starlight from the obscured YSP? To answer this question we use the same approach as Tadhunter et al. (2002). In Table 2.4 we give the bolometric luminosity of the YSP in the nuclear region, where we derived the largest dust obscuration in our SED modelling. \( L_{\text{bol}} \) has been determined from the Bruzual & Charlot (2003) template spectra scaled to our derived parameters of the YSP (Table 2.3). Table 2.4 also gives the amount of light absorbed by dust, assuming \( E(B - V) = 0.3 \) (Table 2.2). From Table 2.4 we see that the amount of absorbed light from the YSP in the nuclear region of B2 0648+27, when re-radiated in the far-IR, can account for a small fraction of the total far-IR luminosity of B2 0648+27 (also note that some nuclear light may have missed the slit, because the seeing was significantly larger than the slit-width; Sect. 2.2). Despite the uncertainties in our derived values, it is likely that there is some additional dust-heating by recent star formation or by the AGN that we do not pick up with the SED modelling.

Using the spectral synthesis models we can also predict how luminous the YSP would have been in the past. Figure 2.11 shows the evolution of the bolometric luminosity of the YSP in the nuclear region. With the assumption that the starburst in its early stage was already
largely obscured by dust in the nuclear region, and most of the starlight was absorbed by this
dust and re-radiated into the FIR, this should provide a good estimate of the FIR luminosity
of B2 0648+27 at that epoch (note that \( L_{\text{FIR}} \) could have been higher in the past if dust
obscuration in B2 0648+27 was not limited to the nuclear region). From Fig. 2.11 we argue
that 0.3 Gyr ago B2 0648+27 had the appearance of an (Ultra-) Luminous Infra-Red Galaxy.

Currently B2 0648+27 has passed its ULIRG-phase. The properties of the YSP, the FIR-
luminosity, the starburst-driven outflow of ionised gas and the H\textsc{i} structure are relics of
the violent recent past of this galaxy. In the current phase of its lifetime the galaxy also
plays radio-AGN activity, although this period of AGN activity likely started long after the
merger event. Regarding the total stellar mass of the YSP and the far infra-red properties,
B2 0648+27 resembles two other radio galaxies (3C 293 and 3C 305 - see also Chapter 6)
studied by Tadhunter et al. (2002). These two radio galaxies are also in a post-ULIRG phase
of their evolution, and a possible time-lag between the star burst event and at least the current
period of radio-jet activity has been suggested.

The host galaxy of B2 0648+27 resembles a so-called E+A galaxy. E+A galaxies have
spectral signatures of an elliptical galaxy as well as strong Balmer absorption lines due to
young stars, but they lack [O\textsc{ii}] emission from ongoing star formation. This last point, how-
ever, is difficult to verify for B2 0648+27, since it is uncertain whether the characteristic [O\textsc{ii}]
and [O\textsc{iii}] emission-lines are created solely by the AGN, or if some low-level stellar-related
component could still be present. Chang et al. (2001) presented H\textsc{i} observations of five E+A
galaxies. One of them contains \( 3.5 \times 10^{9} h^{-2} M_{\odot} \) of H\textsc{i}, revealing that also this system has
undergone a galaxy-galaxy interaction, similar to the case of B2 0648+27.

The ultimate fate of B2 0648+27 is that it will most likely end as a genuine early-type
galaxy. In contrast to the stellar population content, the spatial light-distribution of the optical
galaxy already resembles that of an early-type system (Heisler & Vader 1994). The low
surface density, large-scale H\textsc{i} structure will likely survive for a very long time. Ultimately,
B2 0648+27 will have the appearance of other genuine early-type galaxies that contain a
large H\textsc{i} disk-like structure. An example is NGC 5266, in which star formation is occurring
at a much reduced rate and no AGN activity has been detected (Morganti et al. 1997). Other
examples of H\textsc{i}-rich early-type galaxies, many of which could be products of a past merger
event, are given by van van Gorkom & Schiminovich (1997), Sadler et al. (2000), Oosterloo

2.8 Conclusions

We detect \( 8.5 \times 10^{9} M_{\odot} \) of H\textsc{i} in a large ring-like structure of 190 kpc around the radio galaxy
B2 0648+27. We also find that the light from the host galaxy is dominated by a post-starburst
stellar population. The extended H\textsc{i}-structure and post-starburst stellar population are the
result of a major merger event. There appears to be a significant time-delay between the
merger/starburst event and the current episode of radio-AGN activity.

From the derived properties of the merger and starburst event we conclude that B2 0648+27
represents an important link in the evolutionary sequence between ULIRGs and normal early-
type galaxies. More research is necessary to further investigate the role of the AGN activity
in this respect. The relative proximity of B2 0648+27 allows a detailed study of the physical
processes that occur in this system, which is important for high-\( z \) studies, where major
mergers are much more common.
