Functional plasma membranes from the filamentous fungus *Penicillium chrysogenum* have been isolated with the objective of studying transport processes. The isolation procedure consists of three steps, namely homogenization of cells with a Braun MSK homogenizer, followed by Percoll gradient centrifugation and floatation of membranes in a three-step Nycodenz gradient. This method can be applied to strains which differ significantly in morphology and penicillin-production capacity. Plasma membranes were fused with liposomes containing the beef heart mitochondrial cytochrome-c oxidase. In the presence of reduced cytochrome c, the hybrid membranes maintained a high proton motive force that functions as a driving force for the uptake of the amino acids arginine and valine via distinct transport systems.

For more than four decades penicillins have been commercially produced using the filamentous fungus *Penicillium chrysogenum*. This has prompted intensive research on the biochemistry and metabolic regulation of penicillin biosynthesis [1, 2]. Less information is available on the transport processes of precursors needed for the production of penicillin. The biosynthesis of penicillin proceeds in at least three processes of precursors needed for the production of penicillin. This has prompted intensive research on the structural and functional properties of plasma membranes. One or more of these transport steps may be coming limited during the production of penicillin by the industrial strains that are presently used. Studies with intact mycelia demonstrate that *P. chrysogenum* contains transport systems that may play a crucial role in the biosynthesis of penicillin [5, 6].

Whole cells and, in particular, intact mycelia, are inadequate for transport studies as metabolism and compartmentalization of the transported compounds may interfere with a reliable interpretation of the results. Also, the morphology of mycelia differs for various strains. These problems can be avoided by the use of plasma membrane vesicles that are devoid of metabolic activities. Plasma membranes are routinely isolated from a wide variety of organisms and cell types. Filamentous fungi are a remarkable exception to this rule since only for a few species have isolation procedures been described [8–10]. For these few procedures mainly the preparation of inside-out vesicles has been described, while in the case of right-side out vesicles no convenient method is available to energize the membrane. Although the *P. chrysogenum* plasma membranes contain a P-type H⁺-translocating ATPase, ATP cannot be used to energize right-side out membrane vesicles since when added from the outside ATP will not reach the catalytic side. Alternatively, artificially imposed ion-gradients can be used, but the application of this technique is limited as gradients rapidly decay. To study proton-motive force (Δp)-dependent transport systems, plasma membranes may be fused with liposomes containing an accessible primary proton pump. This approach has successfully been applied to both bacterial and yeast plasma membranes [7]. After fusion, the hybrid membranes are usually endowed with a low ion-permeability, and are thus able to sustain a high Δp for a considerable period of time.

In this study we present an isolation procedure that yields closed, transport-competent plasma membrane vesicles from the filamentous fungus *P. chrysogenum*. This procedure can be used for different strains. By fusing the plasma membranes with liposomes containing the beef heart mitochondrial cytochrome-c oxidase, a hybrid system is obtained that is active for the Δp-dependent uptake of amino acids. This study therefore demonstrates amino acid transport in plasma membranes derived from a filamentous fungus.

**EXPERIMENTAL PROCEDURES**

**Organism and culture conditions**

*P. chrysogenum* strains Wisconsin 54-1255 and Panlabs P2 (kindly supplied by Gist-brocades NV) were grown on production medium (pH 6.5) as described by Lara et al. [11] supplemented with 10 mM glutamate and 10% (mass/vol.) glucose. Cultures were incubated for approximately 70 h in a rotary shaker at 200 rpm and 25°C. Wisconsin strain 54-1255 was previously cultured for 24 h on production medium with the omission of phenylacetic acid and lactose, contain-
Plasma membrane isolation

Mycelia were harvested by filtration and washed with an equal volume of 0.9% (mass/vol.) NaCl. All subsequent steps were performed at 4°C. Cells were suspended in cold 25 mM Mops/KOH, pH 7.2, 0.25 M sucrose, 5% (mass/vol.) glyc erol, 1 mM MgCl2, 2 mM dithiothreitol, 1 mM EDTA, 1 mM phenylmethylsulfonyl fluoride (PhMeSO4F), 0.15 mM tetra caine, 1 μg/ml leupeptin and 1 μg/ml pepstatin (buffer A), at 12.5 mg/ml and 7.5 mg/ml (dry masses) in the case of the P2 and Wisconsin 54-1255 strains, respectively. A 75-ml glass homogenizer for 2 min at full speed with cooling by liquid carbon dioxide expansion. Whole cells and debris were removed by centrifugation (3000×g for 5 min in a Beckman CS-6R swing-out rotor; the supernatant is referred to as the homogenate). Percoll was added to the supernatant (24%, final concentration) and the mixture was centrifuged for 30 min at 30000×g in a 45 Ti rotor. The upper band, which contained sealed plasma membranes, was removed and diluted fourfold with buffer A (the remainder of the Percoll gradient is referred to as fraction 1). Percoll was removed by centrifugation for 2 h at 100000×g in a 45 Ti rotor. Membrane pellets (on top of the Percoll pellet) were collected and suspended in buffer A (the final volume was 5% the volume of homogenate used; the supernatant is referred to as fraction 2). The membrane suspension (4.8 ml) was mixed with a stock solution of 50% (mass/vol. in buffer A) Nycodenz (Sigma; 3.2 ml), and poured into a thick-walled tube. Sub sequently, 6 ml 15% (mass/vol.) Nycodenz (in buffer A) and 4 ml buffer A were added on top of this mixture. The gradient was centrifuged in a SW 28 rotor for 1.5 h at 90000×g. Sealed plasma membranes were recovered as a white band at the interphase of 15% Nycodenz and buffer A. Interphases were collected and diluted tenfold with buffer A (the remainder of the Nycodenz gradient is referred to as fraction 3). The diluted membrane suspension was centrifuged for 30 min at 25000×g in a SS34 rotor, and the plasma membranes, recovered as a pellet, were suspended in a small volume of buffer A and were stored under liquid N2.

Marker enzyme activities

Vanadate-inhibited ATPase activity was determined as described by Widell et al. [12] at pH 6.3. Triton X-100 was added to a final concentration of 0.05% (mass/vol.). ATP hydrolysis was measured by the release of inorganic phosphate with malachite green [13] in the presence of 0.1% (mass/vol.) Triton X-100. Nitrate-sensitive ATPase activity (inhibition by 25 mM nitrate) was determined at pH 7.5 in the same way as vanadate-inhibited ATPase activity. Cytochrome-c oxidase was determined at pH 7.5 as described by Storrie et al. [14], and glucose-6-phosphatase was determined in the presence of 0.1% (mass/vol.) Lubrol PX using the coupled assay described by Gierow et al. [16]. Measurements were performed with an Aminco DW2000 spectrophotometer. α-D-Mannosidase was determined at pH 5.5 in the presence of 0.1% (mass/vol.) Lubrol PX, using a fluorometric assay described by Faber et al. [15]. Measurements were performed on a Perkin-Elmer LS5OB luminescence spectrometer. All marker enzymes were assayed at 25°C.

Transport studies

Uptake of the amino acids arginine and valine was studied at 25°C. Cells were suspended in 50 mM potassium phosphate (pH 6.5) at final densities of 10 mg/ml (P2) or 6 mg/ml (Wisconsin 54-1255; dry masses). l-[14C]Arginine (Amersham, 38 Ci/mol) or l-[U-14C]Valine (Amersham, 28 Ci/mol) were added to the cell suspension to 30 μM. At given time intervals, samples of 0.5 ml were taken, added to 2 ml ice cold 0.1 M LiCl, and immediately filtered on 0.45-μm pore-size diameter cellulose-nitrate filters (Schleicher &
Cells were de-energized by preincubation with the protonophore carbamoyl-cyanide-m-chloro-phenylhydrazone (CF$_2$O-$\text{Ph}$C(CN)$_2$, 10 μM) for 54-1255 strain (right panel) is shown for both a partial purified membrane fraction obtained after the Percoll gradient step (●) and for the final plasma membrane fraction (■).

Isolation of plasma membranes

Plasma membranes were isolated from two P. chrysogenum strains, i.e. Wisconsin 54-1255 and Panlabs P2. These strains differ significantly in morphology and in their capacity to produce penicillin. A final penicillin titre of 25 mM can be reached by the P2 strain, while the Wisconsin 54-1255 strain produces approximately tenfold lower titres. P. chrysogenum possesses a thick and rigid cellular wall and therefore only a few homogenization procedures can be used to break whole cells. Fast mechanical disruption of mycelia with glass beads using a Braun MSK homogenizer appeared to be the most convenient method. Short homogenization times with large glass beads were used to prevent excessive disruption of cell organelles. Within 2 min, more than 95% of the cells were broken. Under these conditions, at least 70% of the mitochondria remained intact as judged from the latency of malate dehydrogenase activity. After homogenization and removal of whole cells and debris, plasma membranes were isolated by Percoll gradient centrifugation and a three-step Nycodenz gradient. Depending on the construction of the Nycodenz gradient, a second fraction of plasma membranes at 1.15–1.17 g/ml was obtained. These plasma membranes are highly permeable to protons and, even after fusion with liposomes containing cytochrome-c oxidase, no substantial proton gradient was generated.

To determine the extent of contamination by other membranes, membrane fractions were characterized with the use of biochemical and morphological markers as described by Morrè et al. [28]. Plasma membranes from P. chrysogenum contain a vanadate-sensitive P-type ATPase that proved to be a convenient and reliable marker. Like other plant and fungal P-type ATPases [12, 29], the ATPase activity is dependent on magnesium and is stimulated by potassium. Furthermore, the activity is significantly inhibited by vanadate (100 μM), while azide (<5 mM), nitrate (<50 mM) and oligomycin (<100 μM) are ineffective. The specific activity of the vanadate-sensitive ATPase increased approximately 25-fold during the isolation procedure (Fig. 1, Table 1). Cytochrome-c oxidase, a-D-mannosidase and glucose-6-phosphatase were used as markers for the inner mitochondrial membrane, vacuolar membrane and the endoplasmic reticulum, respectively. a-D-mannosidase is only loosely attached to the vacuolar membrane [30], therefore several control experiments were performed to ensure that the measured activities reflected the actual content of vacuolar membranes in different fractions. All a-D-mannosidase activity could be pelleted by centrifugation at 100000 g for 1 h, and the sedimentation of a-d-mannosidase and nitrate-sensitive ATPase activities coincided during several differential centrifugation steps (data not shown). From the marker enzyme activities, it can be con-
Table 1. Marker enzyme activities and protein content of fractions obtained during the isolation of plasma membranes from the *P. chrysogenum* strains P2 and Wisconsin 54-1255. Data are based on the use of approximately 10 g mycelia (dry mass) as the starting material. Fractions were obtained as described in the Experimental Procedures section. The H+-ATPase activity is the vanadate (100 μM)-sensitive activity. Values in parentheses indicate the total activity (%). —, not determined.

cluded that the majority of contaminating membranes is removed by the Percoll gradient step. The specific activity of the plasma-membrane ATPase increased approximately eightfold for both strains by this step. Remaining contaminants were effectively removed by the three-step Nycodenz gradient. For both strains, an approximately similar increase in specific activity of the plasma membrane ATPase was obtained although the yields differed (Table 1).

Inhibitor studies with homogenates of both *P. chrysogenum* strains revealed the presence of three predominant ATPase activities that differed in pH optimum and sensitivity towards inhibitors (Fig. 1A). The activities can be attributed to a vanadate-sensitive P-type ATPase with pH optimum of pH 6.3, a nitrate-sensitive V-type ATPase with an intermediate pH optimum of pH 7.5, and an azide-sensitive F,F₁-type ATPase with a pH optimum of approximately pH 9. The purified plasma membranes showed only a high ATPase activity towards inhibitors (Fig. 1B). The activities can be attributed to a vanadate-sensitive P-type ATPase with pH optimum of pH 6.3, a nitrate-sensitive V-type ATPase with an intermediate pH optimum of pH 7.5, and an azide-sensitive F,F₁-type ATPase with a pH optimum of approximately pH 9. The purified plasma membranes showed only a high ATPase activity at approximately pH 6 (Fig. 1B), while P2 membranes contained contaminating vacuolar membranes as indicated by a small peak in the ATPase profile at approximately pH 7.5 (Fig. 1B).

Phosphotungstic acid staining was used as a morphological marker for the plasma membranes (Fig. 2). Under appropriate conditions, phosphotungstic acid stains specifically plant and fungal plasma membranes [17]. Whole cells and protoplasts of *P. chrysogenum* showed a distinct staining of the plasma membrane only (Fig. 2A). Morphometric determination of the amount of membranes stained in the final band (data not shown). Plasma membranes of the Wisconsin 54-1255 strain revealed a strong difference in particle density between the P-face (cytoplasmic, convex) and the E-face (data not shown). After fusion with cytochrome-c oxidase vesicles, this difference was less pronounced and the particle distribution was intermediate between that of cytochrome-c oxidase vesicles and plasma membranes (Fig. 3C). After fusion, no membranes with the particle density and distribution of plasma membranes could be observed indicating that all plasma membranes had fused with cytochrome-c oxidase vesicles.

**Fusion of membrane vesicles**

For transport studies, plasma membranes were fused with cytochrome-c-oxidase-containing vesicles by the freeze-thaw method. Freeze fracture images of plasma membranes (Fig. 3B) from the Wisconsin strain revealed a strong difference in particle density between the P-face (cytoplasmic, convex) and the E-face (data not shown). After fusion with cytochrome-c oxidase vesicles, this difference was less pronounced and the particle distribution was intermediate between that of cytochrome-c oxidase vesicles and plasma membranes (Fig. 3C). After fusion, no membranes with the particle density and distribution of plasma membranes could be observed indicating that all plasma membranes had fused with cytochrome-c oxidase vesicles.

**Orientation of membrane vesicles**

Electron microscopy and Nycodenz gradient centrifugation indicated that most of the isolated plasma membrane vesicles were closed and unilamellar with a diameter of 300–800 nm. The sidedness of the plasma membranes and hybrid membrane vesicles was determined by inhibition of ATPase activity by trypsin. Since trypsin cannot penetrate the membrane, the catalytic domain of the ATPase will not be digested when the cytoplasmic surface is located on the inner face of the membrane. Plasma membranes of the Wisconsin 54-1255 strain are almost completely right-side out (Table 3) as the ATPase was inactivated only when Triton X-100 was present during trypsin digestion. This observation was confirmed by freeze-fracture studies (data not shown). Plasma membrane vesicles obtained from the P2 strain were more

**Properties of *P. chrysogenum* plasma membranes**

Some general properties of the *P. chrysogenum* plasma membranes are summarized in Table 2. The density of plasma membranes was assessed by isopycnic sucrose gradi-

heterogenous in orientation, and approximately 50% ATPase activity was accessible from the outside. After fusion of the Wisconsin 54-1255 plasma membranes with liposomes, and subsequent sizing through extrusion, some 'scrambling' of the orientation of the ATPase took place (i.e. approximately 25% of the activity was accessible). The diameter of the fused membranes was 190–240 nm (data not shown).

Amino acid transport

Based on transport studies in mycelia (Fig. 4A and C), the amino acids arginine and valine were used to analyze the transport activity of hybrid membrane vesicles. The uptake of arginine was approximately five times higher in Wisconsin 54-1255 mycelia as compared to the P2 strain. Valine accu-

Fig. 4. Uptake of L-arginine and L-valine in mycelia and hybrid membranes. Uptake of arginine (○, ○) and valine (▽, ▽) in mycelia of the Wisconsin 54-1255 strain (A) or the P2 strain (C). Closed symbols represent uptake under energized conditions, open symbols represent uptake after previous incubation with CF3OPhC(CN)2. The uptake of arginine (●, △) or valine (▽, ▽) in hybrid membranes from the Wisconsin 54-1255 strain (B) or the P2 strain (D) are also shown. Closed symbols represent uptake after the addition of ascorbate/Ph(NMe3)2/cytochrome c, open symbols represent uptake without the addition of redox mediators or after the addition of CF3OPhC(CN)2.

DISCUSSION

Our primary objective with P. chrysogenum is to study specific transport processes that are associated with penicillin production. Therefore, an isolation procedure for pure plasma membranes was developed. Whole cells, instead of protoplasts, were used as starting material for the isolation of plasma membranes because of the ease by which protoplast can be obtained from P. chrysogenum differs markedly from strain to strain, and depends strongly on growth conditions and age of the culture. After fusion of the plasma membranes with cytochrome-c oxidase vesicles, a Δp can be generated that drives the uptake of different amino acids via transport systems that reside in the fungal plasma membrane. The isolation procedure is applicable to different strains, although different yields are obtained. Cytochemical staining with phosphotungstic acid was used to determine the absolute plasma membrane content of the fractions with the highest purity. This method permits a direct assessment of the purity of an isolated fraction [12].

The plasma membranes derived from the Wisconsin and P2 strains differed significantly in orientation. The cause of this remarkable difference is obscure, but one may speculate that the cytoskeleton is more firmly attached to the plasma membrane of the Wisconsin strain as compared to the P2...
strain. The purified plasma membranes showed a density and sterol content that is typical for fungal and mammalian plasma membranes [34]. Moreover, the vanadate sensitive ATPase of the membranes is characteristic of plasma-membrane-associated P-type ATPases. The amino acid uptake studies with the hybrid membranes demonstrate that the system is suitable for the study of active transport processes. The transport activity for arginine and valine purified with the plasma membranes, indicating that this activity is not due to remaining minor contaminants. Since uptake was driven by the AP (inside negative and alkaline), transport activity cannot be due to vacuolar contaminants as the organelles contain proton/solute antiprot systems [30].

In conclusion, this study demonstrates the isolation of *P. chrysogenum* plasma membranes that are active for solute uptake after fusion with cytochrome-c oxidase vesicles. This system is currently being used to characterize the uptake of penicillin precursors and the mechanism of antibiotic excretion.

We thank J. Zagers for preparation of the freeze-fracture replicas and K. Sjollema who made the ultrathin sections, carried out the phosphotungstic acid staining and provided the electron micrographs. We also thank Gist-brocades NV for helpful recommendations and technical support. This research was supported by the Netherlands Organization for Scientific Research (Nederlandse Organisatie voor Wetenschappelijk Onderzoek) and by a grant from the Royal Gist-brocades NV, Delft, The Netherlands.
