ABSTRACT

In integrated light, some color-color diagrams that use optical and near-infrared photometry show surprisingly orthogonal grids as age and metallicity are varied, and they are coming into common usage for estimating the average age and metallicity of spiral galaxies. In this paper we reconstruct these composite grids using simple stellar population models from several different groups convolved with some plausible functional forms of star formation histories at fixed metallicity. We find that the youngest populations present \( t < 2 \) Gyr dominate the light, and because of their presence the age-metallicity degeneracy can be partially broken with broadband colors, unlike older populations. The scatter among simple stellar population models by different authors is, however, large at ages \( t < 2 \) Gyr. The dominant uncertainties in stellar population models arise from convective core overshoot assumptions and the treatment of the thermally pulsing asymptotic giant branch phase and helium abundance may play a significant role at higher metallicities. Real spiral galaxies are unlikely to have smooth, exponential star formation histories, and burstiness will cause a partial reversion to the single-burst case, which has even larger model-to-model scatter. Finally, it is emphasized that the current composite stellar population models need some implementation of chemical enrichment histories for the proper analysis of the observational data.

1. INTRODUCTION

Many recent works on age estimation of spiral galaxies have used the surprisingly orthogonal color-color grids that combine optical and near-infrared colors (e.g., Bell & de Jong 2000; MacArthur et al. 2004). The “surprise” comes from a long list of previous works starting with Worthey (1994) that showed that age effects and metallicity effects in old stellar populations are very similar on colors, i.e., the age-metallicity degeneracy problem. Age and metallicity vectors projected onto color-color diagrams from simple stellar populations are not orthogonal, but lie nearly parallel to each other so that age effects and metallicity effects are indistinguishable. The purpose of this study is to investigate whether the new, seemingly successful method to break the age-metallicity degeneracy problem. The benefits of near-IR photometry combined with optical photometry have been addressed by many groups and applied to wide variety of stellar systems (e.g., de Jong 1996; Puzia et al. 2002; MacArthur et al. 2004; Larsen et al. 2005; Kundu et al. 2005; James et al. 2006). The basic claim is that age-sensitive main-sequence turn-offs (MSTOs) dominate the visible band, while metallicity-sensitive giant branches dominate the near-IR, and that the photometric behavior of these two evolutionary regions is sufficiently different to provide diagnostic power in terms of deriving average ages and metallicities.

It is important to note, however, that the orthogonal grids that appear in the literature are not simple stellar population (SSP) models, but composite stellar population (CSP) ones. The CSP models that we study here are different from the SSP ones in that CSP models are made by convolving SSPs with some plausible star formation histories (SFHs) at fixed metallicity and fixed initial mass function. Obviously, SSP models that consist of a single age and a single metallicity are not good representations of the protracted and ongoing SFH of spiral galaxies.

Before we reconstruct and assess the composite models, however, we investigate the SSP models in detail because they are the building blocks of the composite models. We will compare several different groups’ SSP models that have become available lately and look into their similarities and differences. In particular, we examine the robustness of stellar population models at ages younger than 5 Gyr because we perceive that these younger ages dominate the behavior of the composite models because of their overwhelming luminosity.

We then adopt an exponentially declining star formation rate (often called a \( \tau \) model—see Table 1) in order to make composite models. We make note of the relationship between SSP and CSP models and what information flows from the simple to the complex. Other issues, such as different chemical enrichment histories, helium abundance, and possible variations of initial mass function (IMF) as a function of metallicity are briefly addressed.

2. STELLAR POPULATION MODELS

Many integrated-light models are now available for those interested in interpreting galaxy spectra and colors. Since we are starting with the observational studies of Bell & de Jong (2000)
and MacArthur et al. (2004), we certainly must include the stellar evolution on which the models of Bruzual & Charlot (2003, hereafter BC03) are based because those are the models adopted by MacArthur and Bell to build their diagnostic CSP models, assuming an exponentially declining SFH at fixed IMF and fixed metallicity. The rather minor impact of adopting different forms of the IMF (e.g., Salpeter 1955; Kroupa 2002; Chabrier 2003) is convincingly demonstrated in MacArthur et al. (2004), so we will not explore IMF variation in any depth, but will stick with a Salpeter (1955) IMF. Besides BC03 models, we will also examine Raimondo et al. (2005; the Teramo group’s SPoT), and Maraston (2005, hereafter M05).

Both HR diagram behavior and SSP photometric models will be examined before we look into CSP models. Of key interest are the effects from convective core overshooting and from the thermally pulsing asymptotic giant branch phase at relatively young ages (100 Myr to 2 Gyr), so we wish to include a variety of different approaches to these aspects of evolution theory.

To do this, we use photometric models that are direct descendants of an evolutionary population synthesis code that has been developed to study the stellar populations of star clusters and galaxies (Lee et al. 2002, 2004) that includes as its evolutionary basis the Y2 isochrones (Yi et al. 2001). However, now that we are extending down to 100 Myr, the Y2 isochrones may not be the best choice for this study because there are no post-RGB stellar models yet for the younger ages. We therefore include the Teramo groups’ isochrones, BaSTI (Pietrinferni et al. 2004; Cordier et al. 2006 March 24).

Fig. 1.—BaSTI-sss (solar-scaled standard; no overshooting) isochrones are compared at 100 Myr and at 1 Gyr for the five metallicities that we illuminate in this study (Figs. 4, 5, 10, and 11). To guide the eye, Z = 0.004 and Z = 0.02 are drawn with dashed lines. Also, the RGB tips are marked by squares at 1 Gyr. Note that the blue loop phase at solar metallicity locates at the hotter side compared to that of Z = 0.008 at 100 Myr in these isochrone sets. Gray lines: Full extension along the TPAGB phases of the BaSTI. [See the electronic edition of the Journal for a color version of this figure.]

Fig. 2.—BaSTI-sss (solar-scaled standard; no overshooting) isochrones are drawn at 100 Myr and 1 Gyr for the five metallicities that we illuminate in this study (Figs. 4, 5, 10, and 11). To guide the eye, Z = 0.004 and Z = 0.02 are drawn with dashed lines. Also, the RGB tips are marked by circles at 1 Gyr. Note that the blue loop phase at solar metallicity locates at the hotter side compared to that of Z = 0.008 at 100 Myr in these isochrone sets. Gray lines: Full extension along the TPAGB phases of the BaSTI. [See the electronic edition of the Journal for a color version of this figure.]

Fig. 3.—Similar to Fig. 2, but Padova00 isochrones are displayed at 100 Myr and at 1 Gyr for the five metallicities. To guide the eye, Z = 0.004 and Z = 0.02 are drawn with dashed lines. The RGB tips are marked by circles where they exist (at 1 Gyr), but they do not go all the way to log L ≈ 3.2 due to convective core overshoot effects. Note also that this isochrone sets are relatively brighter than the ones in Fig. 2 because of overshooting. Moreover, the blue loop phases at 100 Myr are systematically shifting to the right with increasing metallicity compared to the ones in Fig. 2. [See the electronic edition of the Journal for a color version of this figure.]

2.1. HR Diagrams

2.1.1. Effects Due to Convective Core Overshooting

We study effects due to convective core overshooting here. Stars more massive than \( \sim 1 \, M_\odot \), depending on the chemical composition, are known to develop a convective core during their hydrogen-burning phases as a result of the strong dependence of CNO cycle energy generation on temperature. The convective motion in the core could go beyond the physical Schwarzschild boundary, carried by momentum. In principle, this overshooting phenomenon would make a larger helium core, a brighter luminosity, and a longer lifetime because of the increased fuel supply. The chemical composition of the stars determines the exact transition mass of convective core overshoot (e.g., Demarque et al. 2004; VandenBerg et al. 2006). Stellar rotation may affect it as well (Deupree 1998, 2000; Meynet & Maeder 2000). For instance, Girardi et al. (2000) adopt \( \sim 1 \, M_\odot \) as the transition mass independent of chemical composition, even though they gradually change overshooting efficiency in the mass range of \( 1.0 \, M_\odot < M < 1.5 \, M_\odot \). The comparisons of transition mass treatment among several different groups are well described in Gallart et al. (2005, supplement section, Fig. 4).

Figure 1 demonstrates the effects due to convective core overshoot from the BaSTI. In this HR diagram, stellar isochrones with and without overshooting effects are depicted at ages 0.1, 1, 5, and 13 Gyr at solar metallicity. The tracks labeled sss are solar-scaled standard isochrones without convective core overshoot and those labeled sso are solar-scaled isochrones with overshooting effects. It is clearly seen in Figure 1 that stars with convective core overshoot (dashed lines) are generally more luminous and show less-extended blue loop phase at 100 Myr than stars without this phenomenon. Moreover, Figure 1 shows that overshooting effects are more conspicuous at 1 Gyr than at 100 Myr, especially near the MSTO region in the case of the BaSTI isochrones. These dissimilarities will be converted and displayed as integrated-light color differences in Figures 4 and 5.

It is also interesting to find in Figure 1 that the overshooting effects persist even at 5 Gyr for solar metallicity in a minor way. However, overshooting effects should disappear altogether at around 5 Gyr for the metal-poor stars as they become less massive compared to those of solar metallicity at the same age. Pietrinferni et al. (2004) note that, for ages less than \( \sim 4 \) Gyr, models including overshooting provide a “better match” to the color-magnitude diagrams of star clusters in the Milky Way Galaxy. As stars become less massive, however, they develop radiative cores and the issue of overshooting effect eventually vanishes, so convective core overshooting is only important at ages \( t < 5 \) Gyr.

2.1.2. Effects Due to the Treatment of TPAGB Stars

We now investigate the effects of the thermally pulsing asymptotic giant branch (TPAGB) phase. The TPAGB phase is the last stage of AGB evolution. In general, the AGB stars start to appear at \( \sim 30 \) Myr, while RGB stars emerge around 2 Gyr (Gallart et al. 2005; Raimondo et al. 2005; Mucciarelli et al. 2006). Therefore, after the high-mass MS stars and supergiants fade away, it is AGB stars that dominate the integrated bolometric light until full-fledged RGB stars are looming. The lifetime of AGB stars depends on their mass and composition but is of the order of \( 10^7 \) yr, with about 90% of the time spent on the early-AGB phase and the rest on the TPAGB. The TPAGB phase dominates the light in the near-IR at young ages \( t < 2 \) Gyr, even though the number of stars in this phase is small compared with the number of stars in earlier phases. After \( t > 2 \) Gyr, the RGB tip becomes nearly as bright as the AGB tip but is much more numerous populated, by nearly a factor of 10 (Ferraro et al. 2004). In Figure 1 (and in Fig. 2), the TPAGB phases are depicted with gray lines, as described in the BaSTI Web site.

Because of the well-known core mass–luminosity relation of AGB stars (Paczynski 1971), it is shown in Figure 1 that the luminosity of TPAGB stars becomes dimmer as the population becomes older, i.e., the stellar masses decrease. Therefore as Figure 1 graphically illuminates, the TPAGB stars are most important at younger ages, not only because they are brighter at high mass but also because RGB stars do not reach the typical RGB tip luminosity since their cores are not degenerate. However, once stars go all the way to the RGB tip and suffer a helium flash, as the population ages (as their masses become lighter and their cores become degenerate) it is RGB stars instead of AGB stars that dominate the near-IR flux.

Recently, several different groups have investigated this interesting but complex set of stellar evolutionary phases. Vassiliadis & Wood (1993), for instance, predicted that the bolometric luminosity of the tip of the AGB should remain much brighter than the tip of the RGB. As a matter of fact, the brightest stars in some star clusters in the LMC and SMC, SWB IV–VI, are carbon-rich AGB stars, and they are generally about 1 mag brighter in \( K \) band than the tip of the RGB (Mould & Aaronson 1979, 1980; Frogel et al. 1980; Cohen et al. 1981; Ferraro et al. 2004; Mucciarelli et al. 2006). Because of carbon-rich AGB stars, the near-IR colors of these star clusters are much redder than those of older or younger clusters, whereas the optical colors redden more monotonically with cluster age.

In order to incorporate these observational facts, BC03, for example, adopted Vassiliadis & Wood (1993) values to extend beyond the early-AGB and took Groenewegen & de Jong (1993) and Groenewegen et al. (1995) values for the relative lifetimes of carbon-rich TPAGB stars. Recently, Marigo et al. (2003) have successfully reproduced the 2MASS and DENIS observations of the red tail of carbon-AGB stars in the LMC theoretically in the \( (J - K, K) \) diagram using carbon-rich opacities instead of the oxygen-rich opacities of \( M \) giants. They indeed recognize that carbon stars are about 1 mag brighter in \( K \) band than oxygen-rich \( M \) stars. Historically, it was Blanco et al. (1978) who first found that the number ratio of \( C/M \) stars decreases sharply with increasing...
metallicity from the SMC, to the LMC, to the Galactic Bulge. This is because stars with lower metallicities require fewer thermal pulses to change from O-rich to C-rich stars (Liu et al. 2000).

Figures 2 and 3 compare BaSTI and Padova isochrones at 100 Myr and at 1 Gyr for five different metallicities. Figure 2 shows the solar-scaled, standard (no overshooting) BaSTI, while Figure 3 depicts the Padova 2000 isochrones (Girardi et al. 2000; hereafter Padova00) that adopt overshooting effects as a default. There are subtle differences between Figures 2 and 3, mostly because of the input physics that go into each stellar model. First, contrary to the BaSTI-sso isochrones, at 100 Myr the Padova00 isochrones become systematically redder with increasing metallicity, particularly in the blue loop phases. This results in the wide range in $V-K$ color as a function of metallicity in the simple stellar population models based on Padova isochrones, such as BC03. Second, compared to the recent description of full extension along the TPAGB phases of the BaSTI (Fig. 2, gray lines), we deduce that the Padova00 isochrones do not have the TPAGB phase at 100 Myr, but at 1 Gyr they go all the way to the TPAGB luminosity, although they seem to fail to illuminate carbon stars, as Marigo et al. (2003) pointed out. It is also worthwhile to reiterate that Padova00 employs convective core overshooting as a default, and that this makes them, on the whole, brighter than BaSTI-sso. Moreover, at 1 Gyr the RGBs of Padova00 do not go all the way to the tip luminosity because of the overshooting effect, as illustrated in Figure 1.

2.2. Color-Color Diagrams

Having examined the key uncertainties of stellar models at young ages in the HR diagram, we now compare SSP models in color-color diagram. The $B-V$ versus $V-K$ diagrams will be examined first. This is because there are well-established observational data sets of star clusters and galaxies in $BVK$ passbands. Later we will switch to the familiar $B-R$ versus $R-K$ plots that Bell & de Jong (2000) and MacArthur et al. (2004) presented in their papers.

Figures 4 and 5 show several different SSP models at 0.1, 1, 5, and 13 Gyr in the $B-V$ versus $V-K$ diagram. At a given age, five metallicities are delineated as indicated at the bottom right. To guide the eye, solar metallicities are marked by filled symbols at given ages. The solid lines with big open squares are from BC03. In Figures 4 and 5, our SSP computations using the BaSTI with and without convective core overshoot are separately plotted at 0.1, 1, and 5 Gyr of age. Dashed lines with open squares are our models using BaSTI-sss and dotted lines with open circles are BaSTI-sso. The only difference between Figures 4 and 5 is in our SSP computations: we adopt the BaSTI all the way to the TPAGB in Figure 4, while Figure 5 shows the effect of cutting out the TPAGB phases altogether. In this way, we can see the size of the color shifts arising from the TPAGB contribution (e.g., Figs. 1 and 2, gray lines).

The effects due to convective core overshoot are also displayed in Figures 4 and 5. They are dominant, as expected, at young ages only, here exemplified at 100 Myr and at 1 Gyr. In particular, the differences due to overshooting are more outstanding at 1 Gyr than 100 Myr, as expected from the HR diagram from the BaSTI in Figure 1. Moreover, metallicity differences from $Z = 0.0003$...
to $Z = 0.004$ at 100 Myr give rise to significant color differences in Figure 5 because the MS turnoff and blue loops are considerably hotter at $Z = 0.003$ compared to those at $Z = 0.004$, as illustrated in Figure 2. Furthermore, it should be noted that at 100 Myr the colors from our computations (also from the SPoT in Fig. 6 and from M05 in Fig. 7) at solar metallicity are bluer compared to those at $Z = 0.008$ because the blue loop phase of the BaSTI at solar metallicity is hotter than the $Z = 0.008$ blue loop. It is also interesting to find that only BC03’s 100 Myr models cover a wide range in $V - K$ as a function of metallicity: this will later result in the nice orthogonal grids seen in the composite models. By comparing Figures 2 and 3, it can be seen that the continual redward march of the blue loop as a function of metallicity of the Padova isochrones causes BC03’s wide spread in $V - K$.\footnote{The stellar evolutionary phase of the blue loop is notoriously difficult to compute and the metallicity does not seem to be the first constraining parameter that governs that phase (S. Cassisi 2006, private communication).}

Comparing Figures 4 and 5, the models lie more closely together in Figure 5, especially at 100 Myr, indicating that the BaSTI’s TPAGB phases contribute substantial luminosity in the $K$ band.\footnote{Also, bear in mind that BC03’s highest metallicity is Padova94’s $Z = 0.05$ compared to Padova00’s $Z = 0.03$ that we see in Fig. 3.} There are profound color differences caused by convective core overshoot and TPAGB phenomena, especially at 1 Gyr. This can be comprehended by examining the HR diagrams in Figures 1 and 2. At 1 Gyr and solar metallicity, for the BaSTI-ss, the TPAGB phase makes $B - V$ only 0.013 mag redder but $V - K$ 0.614 mag redder. Without considering those TPAGB phases, as indicated in Figure 5, the overshooting effects alone make $B - V$ 0.199 mag bluer and $V - K$ 0.727 mag bluer at 1 Gyr and solar metallicity. They are depicted with vectors in Figure 5. Furthermore, it is important to note that the BC03 models’ highest metallicities go very red in $V - K$ compared to other SSPs at 5 and 13 Gyr. This is possibly because BC03’s highest metallicity is $Z = 0.05$ with $Y = 0.352$ from the Padova94 assumptions, while the others employ the BaSTI at $Z = 0.04$ with $Y = 0.303$.

In Figure 6, BC03 and SPoT models are compared. The solid lines with open triangles are from Raimondo et al. (2005). To guide the eye, solar metallicities are marked with filled symbols. By comparing the SPoT models in Figure 6 with our calculations in Figures 4 and 5, which are similarly based on the BaSTI, it seems that SPoT’s TPAGB treatment (their B1 models with moderate mass-loss rate) is in between our computations of scenarios with and without the Cordier et al. (2007) TPAGB description. For BC03, it is also most important to note that at 100 Myr the wide range of metallicities merely generates small variations, less than 0.2 mag, in $B - V$. This is understandable from Figure 3, where the hot upper main sequence stars counterbalance the relatively cool blue loop phase stars to make an intriguingly narrow range in integrated $B - V$ color at 100 Myr.

BC03 models are compared with M05 models in Figure 7. Solid lines with big open squares are from BC03, while those with crosses are from M05. To guide the eye, solar metallicities are marked with filled and larger symbols at four ages: 0.1, 1, 5, and 13 Gyr. At 100 Myr, M05 models are only given at four metallicities, i.e., $Z = 0.001, 0.01, 0.02,$ and 0.04, so that the bluest color of M05 at 100 Myr is $Z = 0.001$. To extend the high-metallicity end, M05 implemented 3.5 $Z_\odot$, metallicity Padova stellar models from Salasnich et al. (2000) in the fuel-consumption theorem-based models. Here, we show those M05 SSP models that have a blue horizontal branch at the two lowest metallicities. It is

\footnote{BC03 have recently conceded that their treatment of TPAGB phases needs to be revised (see Bruzual 2007).}

\footnote{The SPoT models were developed before BaSTI isochrones have the full extension along the TPAGB phases. They present four different TPAGB cases depending on mass-loss rates. We show their B1 models with moderate mass-loss rate in this study as posted at the SPoT Web site.}
intriguing to note that the most serious differences between two models are manifested at 1 Gyr, to a degree similar to (but more significantly discrepant than) what we have seen from the model comparisons in Figures 4 and 5. This is because of different descriptions of both the convective core overshoot and the TPAGB treatment (Maraston et al. 2006).

3. COMPARISON OF MODELS WITH OBSERVATIONS

Having discussed the theoretical uncertainties in stellar models and their ramifications on the SSP models, we now present a comparison between theoretical models and observational data. In Figures 8–12, observational data from Large Magellanic Cloud (LMC) star clusters are overlaid with BC03, M05, and our computations in the [Fe/H] versus $(B - V)_0$ (bottom) and $(V - K)_0$ (top) plots. LMC star clusters’ integrated $(B - V)$ colors are from van den Bergh (1981). Their reddening and $(V - K)_0$ and SWB types are from Table 4 of Persson et al. (1983). The ages and metallicities of these star clusters are adopted from Table 2 of Pessev et al. (2006). We note, however, that recent measurements of higher metallicity LMC clusters ([Fe/H] > -1.0 dex) by Grocholski et al. (2006) show a very tight metallicity distribution (mean $[Fe/H] = -0.48$, $\sigma = 0.09$). Among SWB types I–III, clusters younger than 100 Myr are depicted with open triangles. According to Frogel et al. (1990), the SWB type V star clusters in the LMC have bright AGBs with carbon stars (see also
Mucciarelli et al. [2006] for recent near-IR color-magnitude diagrams). Indeed, the $V - K$ colors of some of these LMC SWB type V star clusters (solar symbols in Figs. 8–12) are redder than the average trend. The observational scatter in $V - K$ color of LMC SWB types I–III star clusters should be understood by some other mechanism, such as stochastic effects (Santos & Frogel 1997), but certainly not by metallicity (see also Goudfrooij et al. 2006). One of the old SWB VII clusters, NGC 1841, is also indicated in the plots because of its unusually red $(B - V)_0$ color. Its $(B - V)$ is 0.90 according to Table 3 of van den Bergh (1981) and its $E(B - V)$ is given as 0.07 in Table 4 of Persson et al. (1983). However, its peculiarity can be removed if we adopt 0.80 for its $(B - V)$ from Table 1 of Bica et al. (1996) and 0.18 for its $E(B - V)$ from Walker (1990).

Now we take a close look how different SSP models are compared with these LMC star clusters with a wide range of age and metallicity. First of all, LMC star clusters are overlaid on BC03 models in Figure 8. Those four ages (100 Myr, 1.5, 13 Gyr) that are shown in the previous color-color plots are delineated with lines with crosses, triangles, squares, and circles, respectively. To add detail, we also display model predictions at finer age spacings. At solar metallicity, eight 100 Myr increments between 100 Myr and 1 Gyr, and 1.5, 2, 3, and 4 Gyr between 1 and 5 Gyr are connected with dots. Both the $B - V$ and $V - K$ colors of BC03 models become monotonically redder with increasing age at given metallicity. Kerber et al. (2007) recently determined ages for four of the intermediate-age star clusters using deep HST color-magnitude diagrams (CMDs). Using Padova models, the ages of NGC 1856, NGC 1831, NGC 2173, and NGC 2121 were estimated as 300 Myr, 700 Myr, 1.6 Gyr, and 2.9 Gyr, respectively, and they are compared with models in Figures 8–12. It is noted that contrary to $B - V$ colors, $V - K$ colors show some evident mismatch between intermediate-age LMC star clusters and model predictions (see footnote 15).
Second, in Figure 9, M05 models are compared with LMC star clusters. Just like in the previous figure, four ages (100 Myr, 1, 5, 13 Gyr) that are shown in Figure 7 are delineated with thicker lines with crosses, triangles, squares, and circles, respectively. As we mentioned earlier, for a close examination, we now show every 100 Myr increment between 100 Myr and 1 Gyr, and 1.5, 2, 3, and 4 Gyr between 1 and 5 Gyr from her models. We have used crosses, triangles, squares, and circles repeatedly for the description of increasing ages. While the $B - V$ colors become monotonically redder with increasing age at given metallicity, her $V - K$ colors show a sudden leap at 300 Myr because of the onset of the TPAGB. Note that M05 tuned her fuel consumption theorem parameters using the older age estimation of intermediate-age LMC star clusters. The exact epoch of onset will be satisfactorily constrained in the near future with a greater number of detailed deep CMDs of nearby young and intermediate-age star clusters along with the help of improved stellar models (e.g., Kerber et al. 2007; Mucciarelli et al. 2007).

Finally, our calculations with BaSTI are presented in Figures 10–12. Figure 10 shows our calculations employing BaSTI-ssss isochrones with the exclusion of TPAGB phases, while Figure 11 illustrates those with TPAGB phases. It is seen that the $V - K$ colors become significantly redder at younger ages because of the TPAGB phases, whereas they do not affect $B - V$ colors much. The apparent mismatch in $V - K$ colors between our calculations and intermediate-age LMC star clusters lingers even with TPAGB phases. In Figure 12, we add convective core overshooting effects along with a TPAGB using BaSTI-ssss isochrones. It is seen that both $B - V$ and $V - K$ colors become bluer compared to Figure 11 at younger ages because of the convective core overshooting effects. Although this case should be the most realistic one, it does not ameliorate the mismatch between observations and models at $V - K$ colors. It is believed, however, that all these discrepancies will be narrowed down with the improvement of stellar models (e.g., Marigo 2007).

Having studied the model differences and their matches against the observations in $BVR$ photometry, in Figure 13, we switch from $B - V$ versus $V - K$ to $B - R$ versus $R - K$, as Bell & de Jong (2000) and MacArthur et al. (2004) presented their spiral galaxy data in these colors. Figure 13 is similar to Figures 6 and 7, but here BC03, M05, and SPoT SSP models at 0.1, 1, 5, and 13 Gyr are compared in the $B - R$ versus $R - K$ diagram. This is the basis of Figure 14, the composite model grids when the Figure 13 SSP models are convolved with exponentially declining SFHs. In addition, in Figure 13 BC03’s solar metallicity composite models from Figure 14 are shown as big filled squares connected by a thick line (indicating the seven average ages, $\langle t \rangle$, in Fig. 14) to compare SSP and CSP models. According to Figure 11 of MacArthur et al.
4. RESULTS AND DISCUSSION

Composite stellar population models from three different groups (BC03, M05, and SPoT) are shown in Figure 14. BC03 (black lines) and M05 (red lines) are compared in the top panel and BC03 and SPoT (blue lines) are contrasted in the bottom panel. We have generated each model grid using identical star formation rates (SFRs). The simple exponential SFR that we use in this study is

\[ \Psi_{\text{exp}}(t) = \frac{c_{\text{exp}}}{\tau} e^{-t/\tau}, \]  

(1)

where

\[ c_{\text{exp}} = \frac{1}{1 - e^{-A/\tau}} \]  

(2)

and \( A = 13 \) Gyr. The average age by which they are labeled is a mass-weighted average age and at a given \( \tau \), computed as

\[ \langle A \rangle = A - \frac{1 - e^{-A/\tau}}{1 - e^{-A/\tau}} \left( 1 + \frac{A}{\tau} \right) \]  

(3)

For example, a constant star formation rate over 13 Gyr yields an average age of 6.5 Gyr. If weighting by luminosity rather than mass, one arrives at much younger ages. For comparison, we list \( V \) - and \( K \)-band luminosity-weighted ages at solar metallicity for BC03 models along with the \( \tau \) and mass-weighted ages in Table 1. Our mass-weighted age is actually the \( \langle A \rangle_{\text{cutoff}} \) that appears in the third column of Table 1. This is because we have considered the most recent star formation to be truncated at 100 Myr in this study.\(^{17}\) In Table 1, the luminosity-weighted ages are indeed much younger than the mass-weighted ages because young stellar components dominate the light in the composite populations, as can be seen from Figure 13 when SSP ages are compared to the CSP ages.

The models illustrated in Figure 14 are clearly different from one another, although they seem to agree to a certain degree at solar metallicity (delineated with thick lines to guide the eye). The differences arise from the original dissimilarities of simple stellar populations. In fact, the averaging process for the \( \tau \) model CSPs smooths over many of the angularities present in the SSP grids to yield something more regular. It is also worthwhile to note that these composite grids are built at fixed metallicity, without any chemical evolution. The behavior of the CSP models echoes that of the SSP ones, and especially that of the younger components, but not as closely as the CSP ages.

\[^{17}\] Besides the reason that we noted in §2, it is seen in Table 1 that only the \( \langle A \rangle = 5.1 \) Gyr case is affected by the 100 Myr minimum age, and the effect is negligible. Although there is ongoing star formation \( t < 100 \) Myr in spiral galaxies, that mass fraction is not usually a major component (e.g., Hammer et al. 2005).
are much more compact in $R-K$ colors compared to BC03, both at the metal-poor and at the metal-rich side, also echoing their original SSP models.

We have used the same symbols for similar metallicities in Figure 14 in order to make the comparisons easy. The highest metallicities of three models are almost the same: the highest metallicity in BC03 is $Z = 0.05$ with $Y = 0.352$, while the two other are $Z = 0.04$ with $Y = 0.303$ (SPoT) and $0.340$ (M05). The thick lines in Figure 14 are solar iso-metallicity lines for each CSP model. We hope that the fact that different models become similar at this critical metallicity is a robust result and not a coincidence. Reading from Figure 14, a galaxy with colors $B-R = 0.97$ and $R-K = 2.37$ would, in the M05 $\tau$ models, have an age of 5.1 Gyr and $Z = 0.04$, or $[\text{Fe}/\text{H}] = +0.3$ where $[\alpha/\text{Fe}] = 0$. The same galaxy would have (age, $Z$, [Fe/H]) = (7.0, 0.037, 0.27) according to BC03, or (6.7, 0.052, 0.41) according to SPoT. Taking another galaxy as an example, with $B-R = 1.61$ and $R-K = 2.39$, M05 would indicate (age, $Z$, [Fe/H]) = (13, 0.02, 0.00), while BC03 indicates (15, 0.008, $-0.40$) and SPoT indicates (16, 0.012, $-0.22$). The uncertainties appear to be in line with those tabulated in Charlot et al. (1996), about 30% in age. The scatter in abundance may be a bit larger than the 0.1 dex predicted by Charlot et al. (1996). In terms of relative $\Delta Z/\Delta\text{age}$ measurements, such as would be applied to spatial gradient data, Figure 14 yields similar percentage scatter.

Notwithstanding the incorporation of star formation history using the exponentially declining $\tau$ models, Figure 14 is still far from a realistic description of stellar populations of spiral galaxies. This is because even models like those in Figure 14 do not yet include any form of chemical evolution because they are built at fixed metallicity. In Figure 15, we experiment with the same exponential SFR that we have adopted in Figure 14, but with one very simple and useful case of chemical enhancement where metallicity is varied along with age. For this experiment, $Z = 0.0001$ is assigned for the stars that formed at 13 Gyr ago, $Z = 0.0004$ for the stars formed at 11 and 12 Gyr ago, $Z = 0.004$ for the stars formed at 9 and 10 Gyr ago, $Z = 0.008$ for the stars formed at 7 and 8 Gyr ago, $Z = 0.02$ for the stars formed at 2, 3, 4, 5 and 6 Gyr ago, and $Z = 0.05$ is given for the stars that formed at 0.1 and 1 Gyr. These models are marked by big circles in Figure 15, one for each mass-weighted average age, $\langle A \rangle$. In this case with strong age-metallicity relation, the CSP models with older average ages become considerably bluer in $R-K$ because of their (assumed) low metallicity, as most star formation happens at very early cosmic time. Models with younger average ages, on the other hand, become progressively redder because recent star formation has high metallicity.

These models are clearly far from the observations of spiral galaxies (roughly located near the thick line in Fig. 15, according to Fig. 11 of MacArthur et al. 2004) suggesting that this toy model with a strong age-metallicity relation is incorrect. However, the toy model serves to illustrate that a general trend caused by any chemical evolution scheme with an age-metallicity relation will cause a tilt in the model grids. The toy model is an extreme case, but almost any chemical evolution scheme will share the characteristic that star formation starts at low metallicity at early times and works toward high metallicity at late times. This will, in every case, induce a bias in the CSP color-color plots. Clearly, future work should include chemical evolution if coherent age results are the goal.

To summarize our results, the youngest populations in composite stellar population models dominate the light and act to defeat the otherwise universal age-metallicity degeneracy in color-color diagrams that employ optical and near-IR photometry. But scatter from model to model is large at simple stellar population ages $t < 2$ Gyr. The dominant uncertainties in stellar population models arise from the convective core overshoot and the TPAGB phase, but helium abundance may play a significant role at higher metallicities. The various models show notable differences that result in considerably dissimilar composite grids in integrated light. These results suggest that the interpretation of rest-frame near-IR photometry is severely hampered by model uncertainties and therefore that the determination of ages and metallicities of spiral galaxies from optical and near-IR photometry may be harder than previously thought. Another source of cosmic variation could be introduced by the character of the star formation, whether it is smoothly varying like the models or characterized by bursts. Burstiness will cause a partial reversion to the SSP case, which has larger model-to-model scatter than the CSP models. Furthermore, it is emphasized that the current composite stellar population models do need some implementation of chemical enrichment histories for full interpretation of the observational data.

It is a great pleasure to thank Lauren MacArthur, Santi Cassisi, Gustavo Bruzual, Claudia Maraston, Mustapha Mouhcine, Gabriella Raimondo, Alessandro Bressan, Roelof de Jong, Aaron Dotter, and John Blakeslee for many helpful discussions. We also thank the anonymous referee for her/his thoughtful comments and insightful suggestions, which improved this paper greatly. Support for this work was provided by the NSF through grant AST-0307487, the New Standard Stellar Population Models (NSSPM) project.
