Abstract

High-grade astrocytomas are malignant brain tumours which infiltrate the surrounding brain tissue and have a poor prognosis. Activation of formyl peptide receptors (FPR1) on the human astrocytoma cell line U87 promotes cell motility, growth and angiogenesis. We therefore investigated the FPR1 inhibitor, Chemotaxis Inhibitory Protein of S. aureus (CHIPS), as a potential anti-astrocytoma drug.

FPR1 expression was studied immunohistochemically in astrocytomas WHO grades I to IV. With intracellular calcium mobilisation and migration assays, human ligands were tested for their ability to activate FPR1 on U87 cells and on a cell line derived from primary astrocytoma grade IV patient material. Thereafter, we selectively inhibited these ligand-induced responses of FPR1 with an anti-inflammatory compound called Chemotaxis Inhibitory Protein of S. aureus (CHIPS). U87 xenografts in NOD-SCID mice served to investigate the effects of CHIPS in vivo.

FPR1 was expressed in 29/32 (90%) of all grades of astrocytomas. Two human mitochondrial-derived formylated peptides, formyl-methionil-leucine-lysine-isoleucine-valine (fMLKLIV) and formyl-methionil-methionil-tyrosine-alanine-leucine-phenylalanine (fMMYALF), were potent activators of FPR1 on tumour cells. Ligand-induced responses of FPR1-expressing tumour cells could be inhibited with FPR1 inhibitor CHIPS. Treatment of tumour-bearing mice with CHIPS slightly reduced tumour growth and improved survival as compared to non-treated animals (P = 0.0019).

Targeting FPR1 with CHIPS reduces cell motility, tumour cell activation and prolongs survival of tumour-bearing mice. This strategy could be explored in future research to improve treatment results for astrocytoma patients.
Introduction

Astrocytoma is a malignant neoplasm arising from astrocytes within the central nervous system. The tumour aggressiveness ranges from slowly growing low-grade tumours to rapidly growing high-grade tumours. World Health Organization (WHO) grade IV astrocytoma, generally referred to as glioblastoma (GBM), is the most frequently occurring primary malignant brain tumour in adults. Median survival after diagnosis is approximately 7 years for patients with grade II astrocytoma [1], while the majority of grade IV astrocytoma patients have a median survival of only 12-15 months [2]. The current treatment of astrocytoma consists of surgery followed by radiotherapy and chemotherapy. However, this strategy does not target tumour cell migration into surrounding brain tissue, which is a fundamental feature of astrocytoma and is the major reason for treatment failure. Therefore novel drugs that would target tumour spread are urgently needed.

Tumour cell migration and leukocyte trafficking have many similarities [3]. Mechanisms involved in leukocyte migration, such as the expression of G protein-coupled receptors (GPCRs), could offer important clues for drug development. One of such GPCR, Formyl Peptide Receptor (FPR1), was initially identified to mediate leukocyte migration and was characterised by its ability to bind bacterial-derived chemotactic N-formyl peptides, such as N-formyl-methionyl-leucyl-phenylalanine (fMLF) [4,5].

Binding of the bacterial peptide fMLF to its receptor FPR1 causes the activation of phagocytic leukocytes, essential for the innate host defence against microbial infection [4]. More recently, FPR1 was found to be present on tumour cells and has been identified as a factor contributing to their malignant behaviour [6,7].

Agonist binding to FPR1 in high-grade astrocytoma cells elicits a cascade of signal transduction pathways that involve protein kinase B (Akt), phosphatidylinositol 3-kinase (PI3K), mitogen-activated protein kinases (MAPK) and the transcription factor nuclear factor-κB, which are linked with
tumour-promoting cellular processes such as proliferation, migration and angiogenesis [6,8,9].

Mitochondria contain formylated peptides that, analogously to fMLF, have affinity for FPR1, as shown in promyelocytic HL-60 cells [10]. Moreover, the supernatant of necrotic astrocytoma cells contains agonists capable of inducing FPR1 activation, followed by a robust intracellular calcium mobilisation in U87 astrocytoma cells [6]. Therefore we hypothesised that FPR1 activation in astrocytoma cells can be induced by mitochondrial peptides present in the necrotic cell debris, which serve as natural ligands for FPR1.

The FPR1 inhibitor CHemotaxis Inhibitory protein of S. aureus (CHIPS) is an anti-inflammatory compound secreted by S. aureus [11]. This virulence factor directly binds to FPR1 and C5a receptor (C5aR), inhibiting neutrophil responses to bacterial infection [12]. The potency of CHIPS to inhibit FPR1, together with the contribution of FPR1 function to malignant tumour behaviour, prompted us to test CHIPS as a novel inhibitor of tumour cell activation and migration.

In this study we investigated FPR1 expression in astrocytomas WHO grade I to IV. Furthermore we tested relevant human mitochondrial ligands for their capacity to activate FPR1 on U87 astrocytoma cells and then studied the possibilities of selectively inhibiting these effects with CHIPS. Finally, we investigated the effect of CHIPS treatment in a human tumour bearing mouse model.

**Materials and Methods**

**Reagents**

L-glutamine and gentamicin were obtained from Invitrogen Life Technologies (Bleiswijk, the Netherlands). fMLF, ionomycin calcium salt, porcine skin gelatin and Corning® Transwell® polycarbonate membrane inserts (8.0μm
pore size) and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich (Zwijndrecht, the Netherlands). Fluorescein isothiocyanate (FITC)-labeled fMLF and fluo-3 acetoxyethyl ester (Fluo-3-AM) were purchased from Molecular Probes (Leiden, the Netherlands) and mitochondrial peptides fMLKLIV and fMMYALF from Isogen Life Science (de Meern, the Netherlands). Coomassie brilliant blue G-250 was retrieved from Bio-Rad Laboratories (Veenendaal, the Netherlands), Immobilon-P membranes from Millipore Corporation (Amsterdam, the Netherlands), anti phospho-Akt (Thr308) (C31E5E) rabbit monoclonal antibody (mAb, #2965), anti phospho-p44/42 MAPK (Erk1/2) (Thr202/Tyr204) (D13.14.4E) XP® rabbit (mAb, #4370) and rabbit polyclonal antibody against cleaved caspase-3 (#9661S) were purchased from Cell Signalling Technology (Leiden, the Netherlands). Polyclonal rabbit antibody against FPR1 (#ab12990) was purchased from Abcam (Cambridge, UK), Lumi-lightplus Western blotting substrate and Pwo DNA polymerase from Roche Diagnostics GmBH (Mannheim, Germany). Rabbit polyclonal antibody against glucose transporter 1 (GLUT-1), horse radish peroxidase (HRP)-labelled goat anti rabbit and goat anti mouse antibodies were obtained from Dako (Glostrup, Denmark). Protease inhibitor cocktail EDTA-Free 100 x and Halt™ phosphatase from Thermo Scientific (Breda, the Netherlands). Mammalian Protein Extraction Reagent (MPER) was obtained from Thermo Scientific (Etten-Leur, the Netherlands). Quantikine human VEGF ELISA kit was purchased from R&D systems (Abingdon, UK). The 70µm pore size nylon cell strainer was purchased from Beckton Dickinson (Breda, The Netherlands).

**Cells**

The human astrocytoma cell line U87 was purchased from the ATCC (HTB-14). A newly generated cell line was derived from a 44 year old female patient diagnosed with astrocytoma grade IV. Primary material was obtained after approval and following the ethical guidelines of the Institutional Review
Board of the UMCG. Resected tumour tissue was mechanically dissociated, followed by incubation with trypsin at 37°C for 15min, repeated pipetting and filtration through a 70µm cell strainer to obtain single cells. Cells were centrifuged, washed with PBS (phosphate buffered saline, 2.7 mM KCl, 1.8 mM KH₂PO₄, 137 mM NaCl, 10.1 mM Na₂HPO₄, pH = 7.4) and resuspended in culture medium for propagation. The expression of neuronal and glial markers was confirmed by immunofluorescence microscopy and Western blotting (Supplementary Fig. S1A and S1B). Both U87 and the patient derived cell lines were grown in cell culture flasks pre-coated with 1% gelatin from porcine skin and maintained in Dulbecco’s modified Eagle Medium high glucose (DMEM-H) supplemented with 10% foetal calf serum (FCS). The human promonocytic cell line U937 and its transfected sub-line U937-FPR were kindly provided by Dr. Eric R. Prossnitz (University of New Mexico, Albuquerque, NM, USA). Cells were maintained in Roswell Park Memorial Institute medium 1640 (RPMI 1640) containing 10% FCS, 1% L-glutamine and 10µg/mL gentamicin. All cell lines were cultured at 37°C in a humidified atmosphere with 5% CO₂.

**Expression of Chemotaxis Inhibitory Protein of S. aureus (CHIPS) in E. coli**

CHIPS was expressed in E. coli, as described by de Haas et al. [11]. Briefly, the chp gene was amplified by PCR on chromosomal DNA of S. aureus (strain Newman) using Pwo DNA polymerase. The PCR product was cloned into the pTrcHISB vector (Invitrogen, Bleiswijk, the Netherlands) directly downstream of the enterokinase cleavage site. The vector was transformed into TOP10 E. coli, and recombinant CHIPS was expressed and purified according to the manufacturer’s instructions (Invitrogen, Bleiswijk, the Netherlands).

**Ligand binding assay**

5x10⁶ U87 cells expressing FPR1 were incubated for 45min on ice in RPMI
1640 with 1x10^{-5}M fluorescent formylated peptide ligand (fMLF-FITC). After incubation, cells were washed twice, and fluorescence of the cells was measured by flow cytometry (FACSCalibur; Becton Dickinson, Franklin Lanes, NJ, USA). Data were analysed with WinList software (Verity Software House, Topsham, ME, USA).

**CHIPS-FITC binding**

CHIPS was labelled with FITC as previously described [12]. FPR1-expressing U87 cells were incubated with increasing concentrations of CHIPS-FITC (3, 10 and 20µg/µL) for 30min at 37°C in RPMI 1640 containing 0.05% human serum albumin (RPMI/HSA). Subsequently, fluorescence of the cells was measured by flow cytometry and analysed as described above.

**Blocking cellular fMLF-FITC binding with CHIPS**

5x10^5 U87 or U937-FPR cells were pre-incubated with RPMI 1640 medium only or with different CHIPS concentrations (1 and 100µg/mL) for 15min at 4°C. Subsequently cells were incubated for 45min at 4°C in RPMI 1640 medium with 5x10^{-6} M (U87) or 10^{-7} M (U937-FPR) fluorescent formylated peptide ligand (fMLF-FITC). After incubation, cells were washed twice and fluorescence was measured by flow cytometry as described above.

**Ca^{2+} mobilisation assay**

5x10^6 U87, U937-FPR and the patient derived cells were centrifuged twice (10min, 250 x g, at 4°C) in RPMI/BSA and resuspended in 1mL of RPMI/BSA. Intracellular calcium was labelled by adding 2µL Fluo-3-AM to the cell suspension. Cells were incubated for 20min at room temperature on a shaking table, centrifuged twice and suspended in RPMI/BSA. Thereafter patient derived cells were incubated with 1µg/mL CHIPS and U87 and U937-FPR1 cells were incubated with 0, 0.01, 0.1 or 1µg/mL CHIPS for 15min at room temperature. Samples were analysed by flow cytometry as described above.
First, the background fluorescence of cells was measured. Subsequently, cells were stimulated with fMMYALF, fMLKLIV or fMLF peptides in concentrations ranging from in $10^{-8}$M to $10^{-5}$M for U87, U937-FPR and patient derived cells, or with ionomycin as a positive control. Data were calculated as percentage of maximal calcium mobilisation using the following formula: \[
\frac{(MF_{\text{sample}} - bgF_{\text{sample}})}{(MF_{\text{max}} - bgF_{\text{max}})} \times 100\%,
\] in which $MF$ = mean fluorescence with stimulation and $bgF$ = background fluorescence without stimulation. For the maximal MF ($MF_{\text{max}}$), the MF value of cells stimulated with the highest concentration of stimulus was used.

**Chemotaxis assay (Transwell)**

Transwell inserts with 8µm pores were coated with 50µg/mL collagen type I and incubated for 1h at 37°C. Transwell inserts and lower wells were blocked with 1% BSA/PBS overnight at 4°C, thereafter blocking medium was removed and lower wells were loaded with 300µL of fMLF, fMMYALF or fMLKLIV in DMEM + 0.5% BSA in concentrations ranging from $10^{-7}$M to $10^{-10}$M. U87 or U937-FPR1 cells were serum-starved for 2 days. All steps were performed respectively in serum-free DMEM-H and RPMI 1640 medium. After this, $6 \times 10^5$ cells per mL were harvested and incubated for 15min with control medium or 10µg/mL of CHIPS medium. Subsequently, $1 \times 10^5$ cells per well in 150µL serum-free DMEM-H or RPMI 1640 medium were loaded at the top of Transwell inserts.

Cells were allowed to migrate towards concentrations of fMLF or serum-free DMEM-H (U87) or fMLF, fMMYALF, fMLKLIV or serum-free RPMI 1640 medium (U937-FPR1) for 4.5-5.5h at 37°C. After migration, the top surface of the Transwell inserts was cleaned with a cotton swap wetted in PBS. The cells on the bottom surface of the Transwell insert were fixed with 75% methanol/25% acidic acid for 20min and stained with 0.25% Coomassie blue in 45% methanol/10% acetic acid for 20min. Excessive staining of Coomassie blue was removed by washing the Transwell with demi water. Migrated cells
were identified under the microscope at 40 x magnification by counting 10 fields of view in the middle of the filter from left to right.

**Immunoblotting**

Western blot analysis of Akt, phosphorylated Akt (phospho-Akt) and phosphorylated extracellular signal-regulated kinases 1 and 2 (phospho-ERK1/2) was performed. U87 cells (1x10^6) were seeded and starved for 24h, subsequently cells were pre-incubated with culture medium or with 1µg/mL CHIPS for 20min at room temperature. Thereafter, cells were treated with buffer or different concentrations of fMLF (10^-5M, 10^-7M, 10^-8M) for 30min. Cells were then lysed in MPER including 1:100 protease and 1:100 phosphatase inhibitors, sonicated for 3sec and boiled for 5min. Immunoblot analysis of phosphorylated ERK1/2 and Akt and total Akt was performed. Cell lysates were prepared with sample buffer (25 mM Tris-HCl, 5% glycerol, 1% SDS, and 0.05% bromophenol blue, pH = 6.8). Proteins were separated on 10% polyacrylamide gel (SDS-PAGE) and transferred onto Immobilon-P membranes. The membranes were blocked by incubation in Tris-buffered saline (TBS) with 0.01% Tween-20 (TBST) and 5% BSA for 3h at room temperature and then incubated overnight at 4°C with primary antibodies against Akt, phospho-Akt and phospho-ERK1/2 in TBST. After incubation with a horseradish peroxidase–conjugated secondary antibody, the protein bands were detected. Enhanced chemiluminescence with Lumi-lightplus was used for final signal detection.

**MTT assay**

U87 cells (4000 cells per well) were plated in 96-well plates in 200µL of the culture medium. After 1h fMLF, fMLKLIV or fMLALF (0, 10^-5M, 10^-6M, 10^-7M, 10^-8M or 10^-9M) was added to each well. After 1, 2, 3, 4, 5 or 6 days of incubation with or without fMLF, cell proliferation was assessed by MTT assay as described previously [13].
Enzyme Linked Immunosorbent Assay (ELISA)
U87 cells (0.4x10^6 per well) were seeded in a 6-well plate and pre-incubated with culture medium or with 10µg/mL CHIPS for 15min. Cells were treated with fMLF (10^{-7}M) for 24h, supernatant was collected, frozen for VEGF-A analyses and cell numbers were counted. Quantification of VEGF-A protein by ELISA was performed by using the Quantikine Human VEGF ELISA kit according to manufacturer’s instructions. Results were calculated as pg of VEGF-A per 10^6 cells and displayed as normalised values against control (100%) with standard deviations.

Animal model
Male, nonobese diabetic (NOD)/severe combined immune deficient (SCID) mice (6 to 8 weeks old) were purchased from Harlan Laboratories (Horst, The Netherlands). 14 Mice were pre-irradiated with 2Gy and subcutaneously implanted in the dorsal flank with 5x10^6 U87 cells in 100µL PBS. Animals were randomly divided into a treatment group and a control group. Starting from day 1 after tumour cell injection, the animals designated to the treatment group received daily intraperitoneal injections with 1.2mg/kg CHIPS (in a total volume of 100µL PBS) and animals assigned to the control group received PBS intraperitoneally in an equal volume. Tumour size was calculated with the formula: Lw^2/2, where L represents the length of the tumours in millimetres and w the width in millimetres. Animals were sacrificed when reaching the humane endpoint (tumour size > 2cm^3) and tumours were excised, dissected into two pieces, snap frozen or formalin-fixed and paraffin-embedded. 5µm thick sections of paraffin-embedded tumours were subjected to haematoxylin and eosin (H&E) staining and immunohistochemistry was performed to visualise cleaved caspase-3 as an apoptotic marker. All experimental procedures were approved by the Institutional Animal Care and Use Committee (IACUC) and conducted in accordance with institutional ethical regulations for experimental animal care.
Human tissue collection

4µm cryosections of brain tumour specimens of 32 patients diagnosed between 2007 and 2010 with grade I to IV astrocytoma were retrieved from the tissue bank at the Department of Pathology of the University Medical Center Groningen. Tumours were histologically classified with H&E staining according to criteria of the WHO [1]. Tissue samples with representative histological characteristics and a sufficient amount of tissue for analyses were included. Tumour tissues were numerically tagged, based on a national coding system. According to Dutch law, no further Institutional Review and Board approval was required (www.federa.org). Eight pilocytic astrocytomas WHO grade I, 8 diffuse astrocytomas WHO grade II, 8 anaplastic astrocytomas WHO grade III and 8 astrocytoma WHO grade IV were stained for FPR1 expression.

Immunohistochemistry and staining evaluation

Both paraffin-embedded xenografts from the animal study and frozen human tissues were stained immunohistochemically according to standard protocols. The paraffin-embedded tissue was first deparaffinised with xylol, followed by ethanol and transferred in citrate buffer pH = 6.0, heated for 15min at 95°C and cooled to RT. Following steps were the same for frozen and paraffin embedded specimens. Slides were washed with PBS, blocked with 0.33% H₂O₂/PBS buffer for 30min at room temperature and washed again with PBS. Subsequently sections were incubated for 1h at room temperature with polyclonal primary antibodies against cleaved caspase-3, GLUT-1 or FPR1 diluted in 1% BSA/PBS. Tumour sections were then washed with PBS and incubated with peroxidase-coupled goat-anti rabbit secondary antibody in 1% BSA/PBS + 1% AB serum for 30min. After washing with PBS, slides were incubated with peroxidase-coupled anti-goat tertiary antibody in 1% BSA/PBS + 1% human AB serum for 30min followed by 3,3’-diaminobenzidine (DAB) treatment for 10min and rinsed with tap water. Counter staining was
performed with hematoxylin for 2min and washed with tap water. Paraffin-embedded U937-FPR cells served as positive control for FPR1 staining. For all sections omission of the primary antibody served as a negative control. Staining evaluation was performed by double-blind scoring using Olympus WH10x-H/22 grid by scoring on high power field (ocular 10x and objective 40x). Quantitative analysis was performed by calculating the percentage of positive cells on three high magnification fields per tumour slide. Subsequently the antigenic load was calculated as described previously [14] by multiplying the percentage of positive cells by their semi-quantitative score. Semiquantitative score ranged in scale from 0 to 4, defined as 0 when no staining, 1 as low intensity staining, 2 as moderate staining, 3 as high intensity staining and 4 as exceptionally intense staining.

For the evaluation of cleaved caspase-3 levels in U87 xenografts, a distinction was made between hypoxic and normoxic areas. As hypoxic areas strongly correlate with the expression of hypoxia marker GLUT-1, [15,16] the regions located adjacently to the necrotic areas were defined as hypoxic zones and positive for GLUT-1. The normoxic areas were defined as the regions surrounding the hypoxic areas containing viable cells and no GLUT-1 expression (data not shown). Both normoxic and hypoxic areas were analysed [17].

**Statistical analyses**

All statistical analysis were performed with GraphPad Prism software. Statistical significance was set at P < 0.05. Kruskal-Wallis one-way analysis of variance was used (followed by Dunn’s multiple comparison post-test) to assess differences in medians of antigenic load, percentage of positive cells between tumour grades. Data are expressed as median with Confidence Interval (CI) of 95%. A non-parametric Student’s t-test was performed to asses differences in VEGF-A expression. Data analyses on animal survival was performed using a Log-Rank (Mantel Cox) test.
Results

FPR1 is expressed in all grades of astrocytoma specimens

FPR1 expression was observed in all astrocytomas except for one pilocytic astrocytoma (WHO grade I), one diffuse astrocytoma (WHO grade II) and one glioblastoma (WHO grade IV). Low grade diffuse astrocytomas are often characterised by fibrillary astrocytes with irregular and elongated nuclei embedded in a fibrillary matrix [18]. FPR1 expression in grade I astrocytomas was less pronounced on the cell membrane while highly expressed in the fibrillar structures (Fig. 1A). In contrast, on grade II astrocytoma specimens, mainly the membrane FPR1 expression was observed, mostly with intermediate staining intensity (Fig. 1B). In higher grade astrocytomas with bulky cytoplasm, a weak cytoplasmic and strong perinuclear staining was observed (Fig. 1C and D). In grade I and II astrocytomas, over 70% of tumour cells were FPR1-positive with a homogeneous cytoplasmic staining pattern with moderate to high staining intensity (Fig. 1A and B). In grade III astrocytomas (Fig. 1C) 70% of tumour cells were FPR1 positive, but the expression pattern was less homogeneous although with high intensity. In grade IV astrocytomas, 40% of tumour cells were FPR1-positive. One grade IV astrocytoma showed exceptionally high staining intensity, while the other 7 showed strong positivity. The distribution of the staining throughout the tissue was heterogeneous (Fig. 1D). The percentage of positive cells in grade IV (33%) astrocytomas was lower (P < 0.05) than grade I (59%) and grade III (63%) astrocytomas (Fig. 1E). The antigenic load of grade IV astrocytomas was also lower compared to other grades (Fig. 1F). However, only the difference in antigenic load between grade III and grade IV astrocytomas was significant (P < 0.05).

fMLF and CHIPS bind to FPR1-expressing U87

With the FPR1 ligand binding assay we showed that fMLF-FITC binds to the FPR1 expressed on U87 (Fig. 2A). We subsequently performed the CHIPS-FITC
Figure 1. Specimens of human astrocytoma grades I–IV, immunohistochemically stained for FPR1, percentage of positive cells and antigenic load. Micrographs A–D show astrocytic tumours with WHO grades I–IV, respectively. In the low-grade tumours (A and B), diffuse staining can be observed. In the high-grade tumours (C and D), the staining intensity is much less homogeneous. Bars=100 µm. (E) Percentages of positive tumour cells in the various grades of astrocytic tumours (dark line in the box refers to the median, whiskers indicate the 95% CI). The lowest percentage relative to the other three grades is found in glioblastomas (*P<0.05). (F) Antigenic load, the glioblastoma group has the smallest values relative to lower grades (*P<0.05).
binding assay and found a dose-dependent binding of CHIPS-FITC to U87-FPR1 expressing cells (Fig. 2B).

**CHIPS blocks fMLF-FITC binding to U87 and U937-FPR1 cells**

We investigated the ability of CHIPS to block fMLF-FITC binding to FPR1 on

![Figure 2](image-url)
Inhibition of FPR1 in high-grade astrocytoma by CHIPS

U87 and U937-FPR cells. Preincubation with 1 and 100µg/mL CHIPS resulted in dose-dependent inhibition of fMLF-FITC binding on U937-FPR cells (Fig. 2C). In U87 cells 100µg/mL of CHIPS resulted in 81% ± 16% inhibition of fMLF-FITC binding, whereas this effect was not observed after preincubation with 1µg/mL CHIPS (Fig. 2D).

CHIPS inhibits formylated peptide-induced calcium mobilisation

The hallmark of chemokine receptor activation is a rapid and transient increase in the free intracellular calcium level upon ligand binding. This signalling pathway was used to examine whether CHIPS-FITC not only binds FPR1, as demonstrated with the CHIPS-FITC binding assay, but also inhibits the activation by its natural ligand fMLF and mitochondrial peptides fMMYALF and fMLKLIV. U87 cells responded to increasing amounts of fMLF in a dose-dependent manner with intracellular calcium mobilisation (Fig. 3A, control line). We could decrease calcium mobilisation up to 60% with 1µg/mL CHIPS in U87 cells compared to control cells (Fig. 3A). Similarly, U937-FPR cells showed intracellular calcium release following stimulation with fMLF (Fig. 3B) and with both mitochondrial peptides fMLKLIV (Fig. 3C) and fMMYALF (Fig. 3D). Treatment with increasing CHIPS concentrations caused a dose-dependent inhibition of calcium mobilisation (Fig. 3B-D). Finally we used patient derived cells which responded in a dose-dependent manner with intracellular calcium release. This could be decreased up to 70% with 1µg/mL CHIPS (supplementary data).

Overall, with the intracellular calcium mobilisation assay we showed that not only fMLF, but also fMLKLIV and fMMYALF are agonists for FPR1 as demonstrated in both U937-FPR1 and U87 cells. Moreover, CHIPS can potently inhibit FPR1-mediated calcium mobilisation in U937-FPR, U87 and patient derived cell lines.

CHIPS inhibits formylated peptides-induced migration of U87 and

migration and proliferation assays, respectively. CHIPS inhibited up to 81% of U937-FPR migrating cells towards fMLF (Fig. 4A), while chemotaxis towards DMEM/0.5% BSA was not affected (data not shown). At 10µg/mL, CHIPS inhibited 83% of U937-FPR cells migrating towards fMMYALF (10^{-10}-10^{-7}M) (Fig. 4B) and 80% of U937-FPR cells towards fMLKLIV (10^{-10}-10^{-7}M) (Fig. 4C). The migration of U87 cells towards fMLF (10^{-7}M) was 2.5-fold higher relative to the control medium (Fig. 4D). Ten µg/mL of CHIPS completely abolished the migration of U87 cells towards 10^{-7}M fMLF (Fig. 4D). However, formylated peptides did not induce proliferation of U87 cells with formylated peptides (data not shown).

**Figure 5.** Inhibitory effects of CHIPS on fMLF-induced phosphorylation of AKT, ERK1/2 and total AKT (Western blot) and on VEGF-A excretion (ELISA) in U87 cells. (A) Representative immunoblot showing the effects of CHIPS on fMLF-induced phosphorylation of AKT, ERK1/2 and total AKT when incubated with fMLF in U87 cells. (B) Levels of VEGF-A protein in supernatants of U87 cells. Cells were preincubated with or without 10 µg/mL CHIPS and treated with fMLF (10^{-7}M) or culture medium (control) for 24 h. Cells preincubated with CHIPS, produced significantly lower VEGF-A excretion upon fMLF treatment compared with fMLF-treated cells without CHIPS preincubation (*P<0.04).

**CHIPS inhibits phosphorylation of key elements in the downstream pathway of FPR1**

The pronounced effects of formylated peptides on calcium mobilisation and cell migration and their inhibition by CHIPS in U87 astrocytoma cells encouraged us to investigate the downstream FPR1 pathway in more detail.
Western blot analysis showed that increasing concentrations of fMLF induced activation of AKT and ERK1/2 in U87 astrocytoma cells (Fig. 5A, lanes 2-4). AKT and ERK1/2 phosphorylation were inhibited by CHIPS (Fig. 5A, lanes 5-7). CHIPS inhibits the upregulation of VEGF-A in fMLF stimulated U87 cells. We investigated the ability of U87 cells to excrete VEGF-A upon stimulation with fMLF and tested whether this could be inhibited by CHIPS. The levels of VEGF-A excretion reached by control cells was 5174 pg ± 1323 per 10^6 cells, average value of control cells was set at 100%. After 24h of incubation with fMLF, U87 cells showed on average 25% ± 9% increased excretion of VEGF-A compared to control. In cells pre-incubated with CHIPS, fMLF could induce only 8% ± 3% of VEGF-A excretion (P < 0.04) compared to control (Fig. 5B).

**In vivo inhibition of tumour growth by CHIPS**

To test the in vivo effects of CHIPS, we subcutaneously implanted U87 cells in NOD-SCID mice. Animals treated with CHIPS showed slight reduction in tumour volume (Fig. 6A). CHIPS-treated mice exhibited a 50% survival of 45 days while untreated animals showed a 50% survival of 41 days. Median survival of treated animals was higher than untreated animals (P = 0.0019) (Fig. 6B).

**Cleaved caspase-3 expression on animal specimens**

We investigated the effects of CHIPS treatment on the induction of apoptosis by analysing the expression of cleaved caspase-3 in U87 xenografts. Within one and the same tumour, normoxic and hypoxic (Glut1-positive) areas can be distinguished. Between these areas significant differences were found in the percentages of cleaved caspase-3 positive cells in treated (normoxic 1.2% and hypoxic 32.1%) and untreated (normoxic 0.6% and hypoxic 24.5%) animals. When comparing normoxic tumour areas between treated and untreated animals, only a small, but significant difference in the percentage of cleaved caspase-3 positive cells was found (treated 0.6%, untreated 1.2%
Figure 6. Tumour formation and progression in xenografts. U87 cells (5x10^6 in 100μL of PBS) were subcutaneously implanted in the right flank of preirradiated NOD-SCID mice. (A) Tumour growth in U87 subcutaneous xenografts treated with placebo (PBS) or CHIPS was examined. Treated animals received daily injections of 1.2 mg/kg CHIPS in 100μL PBS whereas the control animals received daily equal volumes of PBS. Tumour size is expressed as the mean volume in mm^3 and the arrows indicate killed animals as they reached the humane endpoint (volume >2000 mm^3). (B) Survival of tumour bearing mice. Control animals exhibited significantly lower survival compared with treated animals (*P = 0.0019). (C) H&E and cleaved caspase-3 staining in normoxic regions of control and treated animals. (D) Quantification of cleaved caspase-3 staining in hypoxic and normoxic regions of tumours treated with PBS or CHIPS. Treated animals exhibited slight but significantly higher cleaved caspase-3 staining in normoxic areas compared with untreated animals (*P = 0.026).
(P = 0.026)) (Fig. 6C and D). Between the treated and untreated group no 
significant differences were observed in the hypoxic area. These results 
indicate that CHIPS treatment may increase apoptosis induction.

**Discussion**

In this study we investigated FPR1 as an attractive molecular target for the 
development of novel, urgently needed anti-astrocytoma therapeutics. Moreover we explored potency of CHIPS in inhibiting FPR1-mediated cellular 
responses in established astrocytoma cell line U87, a primary patient-tumour 
derived cell line and in a human xenograft mouse model.

Our immunohistochemical analysis showed high FPR1 expression in all grades 
of astrocytomas (I-IV). Despite that relevance for FPR1 targeting is likely to be 
greater in higher grade astrocytomas defined by necrotic areas [1], low grade 
tumours can also acquire angiogenic profiles comparable with glioblastomas 
[19]. This indicates that antagonists of FPR1 could be a valuable treatment 
option for all grades of astrocytoma patients and might be of relevance 
also for low grade astrocytomas, especially when their location precludes 
complete resection [20].

In this study we found that mitochondrial peptides fMMYALF and fMLKLIV, 
that are normally released from necrotic cells, exhibit FPR1-mediated calcium 
flux on FPR1-transfected U937 cell line, but also on U87. This shows for the 
first time that mitochondrial peptides released by necrotic cells serve as 
human ligands for FPR1 expressed on human astrocytoma cells. In addition, 
we demonstrated that the patient-derived astrocytoma grade IV cell line 
expressed functional FPR1, as we could stimulate calcium mobilisation with 
fMLF and inhibit this with CHIPS. This confirms the potential clinical relevance 
of our findings.

Calcium mobilisation initiated by GPCR activation leads to induction of cell 
migration. Indeed, in a study of Yao et al, FPR1 present on CD133+ astrocytoma 
stem cells could be activated by bacteria or host-derived chemotactic agonists.
and lead to intracellular calcium mobilisation and tumour cell chemotaxis [21]. Consequently, in our study CHIPS treatment inhibited the migration on both U87 astrocytoma cells and U937-FPR cells. Taken together, these results indicate that CHIPS is a promising agent to inhibit FPR1 activation on human astrocytoma cells and decrease cell migration, which is an important biological feature of high grade astrocytomas.

The first study investigating the effect of FPR1 inhibition on tumourigenicity of U87 astrocytoma cells was performed in immunodeficient mouse model. In this model, short interfering RNA (siRNA) against FPR1 markedly reduced the tumourigenic potential of U87 cells [6]. This study provided a rationale for targeting the FPR1 in astrocytoma models, however applying these results in the clinical practice remains challenging due to the problems with delivering siRNA to the tumour cells. In our study, we tested CHIPS, administered intraperitoneally, for its potential to inhibit U87 tumour growth in NOD-SCID mice. Although biological effects in terms of differences in tumour volumes could be observed, these were not significant. Notably, animals in the control group reached the human endpoint earlier compared to treated animals (P = 0.0019), proving that CHIPS treatment in vivo prolongs the survival of U87 tumour-bearing mice.

CHIPS is very selective, since it does not affect other chemoattractant receptors present on neutrophils such as the FPR-like 1, complement factor 3a receptor (C3aR), interleukin (IL) 8 receptor alpha (IL-8RA) and beta (IL-8RB), leukotriene B4 (LTB4) receptors, and the platelet activating factor (PAF) receptor [12]. Compared with other well known FPR1 inhibitors like Cyclosporin H and Boc-PLPLP, the affinity and the potency of CHIPS to bind and block FPR1 is 1000-fold higher [22].

The pharmacokinetics and toxicity of CHIPS as an anti-inflammatory drug were investigated in a small phase 1 study. In that study, circulating anti-CHIPS antibodies induced toxicities upon intravenous administration of CHIPS due to pre-existing antibodies (Haas et al, unpublished data). As
the active site for inhibition of FPR1 is located at the N-terminus and is not dependent on 3D-structural conformations, we recently constructed 6-amino acid N-terminal peptide that displays CHIPS activity. Although the peptide is less potent than CHIPS, it was still able to inhibit fMLF-induced neutrophil response [23]. Therefore it represents a good candidate for further development as a clinical FPR1 inhibitor. The development of peptides can easily overcome problems with antigenicity, and peptidomimetics can open the way to enhanced stability in such peptides.

Targeting FPR1 with CHIPS has a relevant clinical rationale due to its interaction with other pathways involved in shaping the aggressive phenotype of glioblastoma. For example, the cross-talk of FPR1 with epidermal growth factor receptor (EGFR) exacerbates the malignant properties of tumour cells like chemotaxis and proliferation. Moreover knocking down both receptors yielded to superior effects compared with depletion of either one [24]. FPR1 activation was also shown to affect VEGF-A and interleukin 8 (IL-8) production by glioblastoma cells after intracranial implantation in nude mice, as tumours formed by cells with silenced FPR1 showed less active angiogenesis, lower expression of both angiogenic factors and reduced tumour volumes [9]. Although we could not find any in vitro differences in fMLF induced U87 cell proliferation as compared to controls, we did find an inhibitory effect of CHIPS on VEGF-A excretion in fMLF induced U87 cell line. This interaction remains particularly interesting in the context of a recent Food and Drug Administration (FDA) approval of bevacizumab (monoclonal antibody against VEGF-A) for the treatment of recurrent grade IV astrocytomas. The approval was based on the results of two phase II clinical trials, which showed that bevacizumab reduced tumour size in part of the astrocytoma patients [25,26]. At the same time controversies arose, based on a study in 37 patients suggesting that this anti-angiogenic drug may alter the recurrence pattern of malignant gliomas [27]. Anti-VEGF therapy can facilitate co-option of normal vasculature and tumour invasion, potentially leading to a more
aggressive tumour phenotype [28-30]. To improve current antiangiogenic therapy in astrocytoma and potentially other tumours, it will be crucial to identify pathways that simultaneously block perivascular invasion as well as angiogenesis.

In summary, mitochondrial peptides present in necrotic tumour material serve as activating ligands for FPR1 on tumour cells. Moreover, CHIPS specifically inhibits cell activation and migration via FPR1 on U87 astrocytoma cells and increases the survival of U87-tumour bearing mice. In addition, FPR1 is present on all grades of human astrocytoma and induces calcium mobilisation in a patient-derived astrocytoma cell line when stimulated with fMLF. We conclude that this receptor constitutes a clinically relevant target. Therefore further development of CHIPS derivatives might well provide a major contribution to current astrocytoma therapy.
