Chapter 2

Coloration of the Chilean Bellflower, *Nolana paradoxa*, interpreted with a scattering and absorbing layer stack model

**Abstract**

The coloration of flowers is due to the combined effect of pigments and light-scattering structures. To interpret flower coloration, we applied an optical model that considers a flower as a stack of layers, where each layer can be treated with the Kubelka-Munk theory for diffusely scattering and absorbing media. We applied our model to the flowers of the Chilean Bellflower, *Nolana paradoxa*, which have distinctly different-colored adaxial and abaxial sides. We found that the flowers have a pigmented, strongly scattering upper layer, in combination with an unpigmented, moderately reflecting lower layer. The model allowed quantitative interpretation of the reflectance and transmittance spectra measured with an integrating sphere. The absorbance spectrum of the pigment measured with a microspectrophotometer confirmed the spectrum derived by modeling. We discuss how different pigment localizations yield different reflectance spectra. The absorbing layer stack model aids in understanding the various constraints and options for plants to tune their coloration.

Chapter 2

Introduction

Floral coloration is in virtually all plant species due to the expressed pigments that selectively absorb incident light in a restricted wavelength range (e.g. Kay et al. 1981, Lee 2007). For example, flowers with blue-absorbing carotenoids are yellow and flowers with blue-green-absorbing anthocyanins are purple (reviewed by Grotewold 2006). Due to the irregular shape and ordering of the petal’s components (e.g. vacuoles) incident light is backscattered in many directions. The diffuse scattering thereby provides a display that is similarly visible under many angles (Wehner and Bernard 1993, Lee 2007, van der Kooi et al. 2015a).

The pigments together with the structure of the cell complexes inside the petals and the flower’s thickness determine the proportion of light reflected by the flowers. Additionally, the epidermal surface structure slightly contributes to the flower’s appearance. When the surface is smooth and flat the flower is glossy, and with a papillose surface the flower is matte (van der Kooi et al. 2014, Papiorek et al. 2014). In other words, the visual signal of flowers depends on the spectral properties and concentration of the expressed pigments, but also on the structure of the inner elements and surface.

Many studies have focused on flower coloration because of its importance for visual signaling to pollinators. The overall floral reflectance has been documented for numerous plant species (e.g. Arnold et al. 2010, Dyer et al. 2012), but rather few quantitative treatments have been attempted to advance our understanding of how light interacts with the inner components of flowers (Lee 2007). Exner and Exner (1910) applied geometrical optics to various flower structures in a first attempt to explain flower coloration (see also Kay et al. 1981, Gorton and Vogelmann 1996, Lee 2009, Gkikas et al. 2015). However, the inhomogeneity of the flower interior makes a detailed optical analysis cumbersome. The presently available powerful computational methods in principle allow calculation of the spectral signatures of any complex structure, but the required knowledge of the spatial distribution of the essential optical parameters, that is, the refractive index and absorption coefficient, is unavailable for any flower. The contribution of the different structures and layers of flowers to the overall visual signal is therefore currently unknown.

Studies on plant leaves showed that the Kubelka-Munk theory for absorbing and diffusely scattering media offers an alternative approach (Kubelka and Munk 1931, Allen et al. 1969a,b). The central parameters in the Kubelka-Munk theory, the absorption and scattering coefficients of the leaves, could be derived from measured reflectance and transmittance spectra.
A scattering and absorbing layer stack model to interpret flower coloration

(Allen et al. 1969a,b). Yamada and Fujimura (1991) expanded this method by treating a leaf as a stack of plates, where each plate has its individual optical properties, which allowed to non-invasively estimate the chlorophyll content of dicotyledonous leaves.

Here, we present a related spectral analysis in which we treat flowers as a stack of absorbing and scattering optical plates. As a basic and exemplary species for our approach we chose the Chilean Bellflower, *Nolana paradoxa* Lindl., because the flower’s anatomy can be considered as consisting of only two, yet quite differently structured layers. Notably the purplish pigment in *N. paradoxa* occurs only in the upper epidermis, causing a distinctly different coloration of the adaxial and abaxial sides. With the combined Kubelka-Munk-layer-stack method we could straightforwardly assess the spectral absorbance of the flower’s pigment. We discuss how the model allows a quantitative analysis of the virtues of various coloration strategies of flowers.

**Materials and methods**

*Flowers and photography*

*Nolana paradoxa* plants were grown from seeds (De Bolster, Epe, Netherlands) in pots with ample irrigation and temperature 20 ± 2°C under a light regime of L:D = 16:8 in the greenhouse of the Groningen Institute for Evolutionary Life Sciences, Groningen, Netherlands. They were photographed with a Nikon D70 digital camera equipped with an F Micro-Nikkor (60 mm, f2.8; Nikon, Tokyo, Japan) macro objective (Fig. 1a,b). Details of the flower’s epidermal surfaces were photographed with a Zeiss Universal Microscope (Zeiss, Oberkochen, Germany) using an Olympus20/0.45 objective (Olympus, Tokyo, Japan) (Fig. 1c-e).

*Floral anatomy*

To examine the structure as well as the pigment distribution, we examined cross sections of the corolla of *N. paradoxa*. Small pieces of the flower were therefore embedded in a 6% solution of agarose (Duchefa, Haarlem, Netherlands) at ~55 °C, i.e. near the solidification temperature, to provide mechanical support to the small floral elements (following Zelko et al. 2012). Together with the agarose, the floral element was cut to ~200 µm thick sections using a sharp razor blade. The sections were then photographed with the Zeiss Universal Microscope in transmission mode (Fig. 1f).
To measure the reflectance and transmittance of the flower corolla, we used an integrating sphere. A deuterium-halogen lamp (Avantes AvaLight-D(H)-S) delivered light, via an optical fiber, to the integrating sphere (AvaSphere-50-Refl). A corolla piece, positioned at the aperture of the integrating sphere, was directionally (and about normally) illuminated from within the sphere at an area with diameter ~5 mm. The reflected light was collected by a second optical fiber, connected to an Avaspec-2048 CCD detector array spectrometer (Avantes, Eerbeek, Netherlands). A white diffuse tile (Avantes WS-2) was used as a reference. For transmittance measurements, an area of about 1 mm of the same corolla piece was illuminated from outside the sphere via an optical fiber. The absorbance spectrum of the flower’s pigment was measured on corolla pieces immersed in water with a microspectrophotometer (MSP), consisting of a xenon light source, a Leitz Ortholux (Leitz, Wetzlar, Germany) microscope and the spectrometer mentioned above. The microscope objective was an Olympus 20/0.45. The measurement area was typically a square with side length ~10 µm. Due to the MSP optics, the absorbance spectra were limited to above ~350 nm.

Flowers treated as a stack of scattering and absorbing layers
In many flowers the composing material is distributed inhomogeneously in differently structured layers, i.e., the upper epidermis, mesophyll and lower epidermis; notably the expression of pigments is often confined to specific layers (e.g. Kay et al. 1981, Lee 2007). Here we consider a flower as to consist of separate layers that can be treated with the Kubelka-Munk theory for scattering and absorbing materials (Kubelka and Munk 1931). We furthermore assumed that the optical properties of the different layers combined (i.e. the whole flower) can be treated with the theory for a stack of reflecting and transmitting plates where for each layer (with number $i$) the reflectance ($r_i$) and transmittance ($t_i$) are known, thus allowing calculation of the stack reflectance ($R_s$) and transmittance ($T_s$) (Yamada and Fujimura 1991, Stavenga et al. 2006). Because the flower’s upper and lower epidermal surfaces slightly affect the reflectance and transmittance of the flowers, they were incorporated in the combined Kubelka-Munk-layer-stack modeling. Using measured reflectance and transmittance spectra, the modeling yielded quantitative estimates of the absorption parameters ($K_i^* = K_i d_i$) and scattering parameters ($S_i^* = S_i d_i$) of the layers, and with known thicknesses ($d_i$) the absorption coefficients ($K_i$) and scattering coefficients ($S_i$) were derived. The detailed modeling procedures are explained in the Appendix.
Results

Appearance and anatomy of *Nolana paradoxa* flowers

The flowers of the Chilean Bellflower, *N. paradoxa*, show a remarkably dissimilar coloration of the adaxial and abaxial sides. At the adaxial side, the corolla has an approximately homogeneous intense violet color (Fig. 1a), although in close-up view the violet coloration is patterned (Fig. 1c). The corolla tube has a paler color (Fig. 1a). In contrast, the abaxial side has a rather unsaturated violet color (Fig. 1b,d), with the vein areas being even more colorless (Fig. 1b,e).

To uncover the origin of the strongly asymmetric coloration, we have studied the anatomy of the corolla. Cross sections revealed that the violet pigment is mostly concentrated...
in the upper epidermal cells (Fig. 1f). The cells of the upper epidermis have a papillose shape, whereas the cells of the lower epidermis create a smoother profile (Fig. 1f).

Floral transmittance and reflectance
To quantify the optical properties of the *N. paradoxa* corolla, we measured transmittance and reflectance spectra with an integrating sphere, applying first illumination of the adaxial side. Different locations yielded very similar spectra (Fig. 2a).

We interpreted the measured spectra of the corolla with a combined Kubelka-Munk-layer-stack model consisting of four layers: the upper surface (layer #1), a pigmented layer (#2), an unpigmented layer (#3), and the lower surface (#4); see the Appendix, Fig. 7b. First we investigated the contribution of the corolla’s surfaces. The reflectance from the petal interior is minimal in the wavelength range where absorption is extreme, that is, in the ultraviolet. The remaining reflectance, which must be mainly due to the surface, was no more than a few percent, in good correspondence with the modeling that yielded as an estimate ~0.03 for the surface reflectance in the ultraviolet. This value is quite compatible for plant material with refractive index of 1.40-1.45 facing air (Gausman *et al.* 1974). Assuming that the surface reflectance is about wavelength independent, we used in the further modeling for both layers 1 and 4 constant reflectance values \( r_1 = r_4 = 0.03 \) and hence transmittance values \( t_1 = t_4 = 0.97 \).

The anatomy indicated that layer 3 was virtually pigmentless (i.e. the absorption coefficient \( K_3 = K_u = 0 \)). The colorless light scattering of this layer suggested a constant, wavelength-independent scattering parameter. We considered a few different scattering parameters, \( S_u^* = 0.0, 0.1, 0.2 \), or, the reflectance \( r_3 = r_u = S_u^*/(1+S_u^*) = 0.0, 0.09, 0.17 \) and the transmittance \( t_3 = t_u = 1/(1+S_u^*) = 1.0, 0.91, 0.83 \) (Appendix Eqs. 10a,b). We note here that the value \( S_u^* = 0.0 \) is in fact an extreme and unrealistic value, because it means that layer 3 is negligible, as with zero absorption and scattering it does not contribute to the flower optics. Consequently, the interior of the corolla then behaves as a single, homogeneously pigmented layer.

As explained in the Appendix (Eqs. 16a,b), we calculated the transmittance \( (t_p) \) and reflectance \( (r_p) \) spectra for the pigmented layer (#2) by combining the reflectance and transmittance properties of layers 1, 3 and 4 with the averaged transmittance \( (T_{ad}) \) and reflectance \( (R_{ad}) \) spectra measured of the adaxial side of the corolla (Fig. 2a,b). Subsequently, using Appendix Eqs. 6a-c, we derived from the \( t_p \)- and \( r_p \)-spectra the absorption \( (K_p^*) \) and scattering \( (S_p^*) \)
A scattering and absorbing layer stack model to interpret flower coloration

parameters of the pigmented layer (Fig. 2c). The absorption parameter spectra demonstrated that the pigment responsible for the flower’s purple color strongly absorbs in the blue-green wavelength range, much less in the violet, and very strongly in the ultraviolet. The absorption parameter spectra of layer 2 calculated with scattering parameter values $S_u^* = 0.0, 0.1, \text{ and } 0.2$ only slightly differed. The calculated scattering parameter spectra of layer 2 showed distinct troughs in those wavelength ranges where absorption is severe; the spectra varied more strongly (Fig. 2c).

Figure 2: Optical characteristics of a *Nolana paradoxa* flower. (a) Two transmittance ($T_{ad}$) and reflectance ($R_{ad}$) spectra of the adaxial side of a corolla measured with an integrating sphere. (b) Transmittance ($t_p$) and reflectance ($r_p$) spectra of the pigmented layer calculated from the average of the measured transmittance ($\overline{T}_{ad}$) and reflectance ($\overline{R}_{ad}$) spectra, using three values for the scattering parameter of the unpigmented layer ($S_u^*$). (c) Absorption ($K_p^*$) and scattering ($S_p^*$) parameter for the pigmented layer calculated from the layer’s transmittance and reflectance spectra of (b).
Absorbance spectrum of N. paradoxa’s pigment

To investigate the pigment of *N. paradoxa* more directly, in addition to the calculations of the pigment absorption spectra using integrated sphere measurements, we immersed pieces of the corolla in water. The immersion served to remove the air from the corolla and thus, by annihilating the refractive index differences, to largely reduce light scattering by the corolla tissue. The absorbance spectrum measured with a microspectrophotometer (Fig. 3) closely resembled that of the calculated absorption parameter ($K_p^*$) spectra of Fig. 2c.

If the $K_p^*$-spectra had been measured in a homogeneously pigmented, non-scattering medium with absorption coefficient $K$ and thickness $d$, the absorbance (or optical density) would have been $D = 0.4343Kd = 0.4343K^*$ (see the Appendix). We therefore converted the $K_p^*$-spectra into absorbance spectra, and indeed the resulting spectra closely approximated the spectrum obtained from the immersed tissue (Fig. 3). As indicated by Fig. 3, with the latter approach we were able to determine the absorbance spectrum in the full ultraviolet-visible-wavelength range, which was not possible with our microspectrophotometer.

Transmittance and reflectance spectra of the corolla’s abaxial side

To quantitatively investigate the effect of the asymmetrical localization of the pigment on the reflectance of the opposite sides of the corolla, we also studied the case when the incident light was coming from the abaxial side. The transmittance spectra then measured with the integrating sphere ($T_{ab}$) were very similar to the transmittance spectra obtained with adaxial illumination ($T_{ad}$) (Figs. 2a, 4a; see also the Appendix). However, the measured abaxial reflectance spectra severely deviated from the adaxial spectra (Fig. 4b).

To understand the measured spectra quantitatively, we calculated the abaxial reflectance with the four layer model, using the same parameter values as in the previous modeling of the adaxial spectra. The parameter set derived with $S_u^* = 0.0$ yielded a reflectance spectrum of the abaxial side identical to the average of the two reflectance spectra measured of the adaxial side ($R_{ad}$; Fig. 2a, 4b); this can be directly understood, because the latter spectrum was used in the calculation procedure of the parameter value set, which implicitly assumed a homogeneous corolla. The reflectance spectrum calculated with $S_u^* = 0.1$ corresponded well with the spectrum measured from an area in between the veins (Fig. 4b, red curve), and the spectrum calculated with a scattering parameter value $S_u^* = 0.2$ approximated the spectrum measured from a vein area (Fig. 4b, blue curve).
Flowering plants advertise their presence to pollinators by displaying colorful flowers. The flower’s inner structures crucially determine the proportion of backscattered and reflected light, and the floral pigments modulate the spectral distribution of the backscattered light by wavelength-selective absorption, thereby creating spectral contrast with the surrounding plant structures (e.g. Chittka and Menzel 1992, Dyer et al. 2012, van der Kooi et al. 2015b).

To gain insight into the consequences of the various ways of pigmentation and scattering encountered in flowers, we measured reflectance and transmittance spectra of *N. paradoxa* with an integrating sphere. We analyzed the spectra with a combined Kubelka-Munk-layer-stack model by treating the corolla as a stack of four layers: two scattering layers, with pigment only in the upper layer, in between two reflecting surface layers. The modeling showed that the surface reflectance was only a few percent, which is probably due to the shape of the epidermal cells (Fig. 1f). The cone-shaped epidermal cells are generally assumed to focus incident light at their pigment (Gorton and Vogelmann 1996), thus causing the local variations in color patterns observed with epi-illumination (Fig. 1c). However, corolla pieces immersed in fluid clearly demonstrated that the pigment in the upper epidermis is variably concentrated in the epidermal cells, resulting in a somewhat patterned image in close-up view (Fig. 1c). An additional and probably functionally more important consequence of the conical shape of the epidermal cells is...
the scattering of incident light into a large spatial angle (van der Kooi et al. 2014, Papiorek et al. 2014), resulting in a matte display that is equally visible from many sides (Wehner and Bernard 1993, van der Kooi et al. 2015a). The local inhomogeneities of the flower interior are another important source of light scattering by the flower’s tissue.

The reflectance spectrum of the abaxial side measured at an area in between the veins could be described by a scattering parameter value of the corolla interior’s unpigmented layer \( S_u^* \sim 0.1 \), in combination with a scattering parameter of the pigmented layer, which in the long-wavelength asymptote is \( S_p^* \sim 0.5 \); for a vein area the corresponding values are \( S_u^* \sim 0.2 \) and \( S_p^* \sim 0.4 \), respectively. In other words, scattering by the pigmented layer and also by the vein areas is strong, because their interior is very inhomogeneous. Scattering by the tissue of the unpigmented layer in between the veins is relatively modest.

From the scattering parameters and the thicknesses of the two interior layers the associated scattering coefficients of the two layers follow. Taking for both layers effective thicknesses of \( \sim 40 \) µm (Fig. 1f), the scattering coefficients of the unpigmented and pigmented layer for the two cases become \( S_u \sim 2.5 \) mm\(^{-1} \) and 5.0 mm\(^{-1} \) and \( S_p \sim 12.5 \) mm\(^{-1} \) and 10.0 mm\(^{-1} \), respectively. At the green absorption peak wavelength (\( \lambda_{\text{max}} = 545 \) nm) the pigment’s absorption parameter is \( K_p^* \sim 1.4 \), so that the absorption coefficient at the peak wavelength is \( \sim 35 \) mm\(^{-1} \). Interestingly, similar values were derived from other flowers (Chapter 3).

The modeling allowed quantitative insight into the flower tissue optics. As predicted for a layer stack, the measured transmittance spectra for different locations and side of illumination were very similar, but the reflectance spectra of both sides were very different (Fig. 4b). Reflectance spectra calculated with the parameter set derived from the adaxial measurements generally agreed with the measured spectra, but minor deviations remained. The calculations assumed that the scattering parameter in the mesophyll layer was a constant, but the scattering probably slightly depends on the wavelength. Also, the chosen approach has some limitations. Firstly, the Kubelka-Munk theory is based on the assumption that the light flux in the media is diffuse, that is, perfectly random. However, in both the reflectance and transmittance measurements with the integrating sphere, the illumination was directional and about normal to the corolla surface. The light flux in the corolla interior will become rapidly diffuse, but this might not yet be the case in the very first, epidermal layer. Furthermore, the inhomogeneously distributed pigmentation will impair a perfectly diffuse light flux. Nevertheless, the very different colors of both sides of the corolla and the associated reflectance spectra are well explained by the
Asymmetric pigment localization and layering of the corolla interior. An asymmetric distribution of pigments is observed frequently throughout the plant kingdom (e.g. Lee 2007) and may serve an economical function.

To investigate the differences between various distributions of pigments quantitatively, we have calculated reflectance spectra for three flower cases (Fig. 5): a - asymmetric pigment distribution with two equally thick layers, one pigmented and one unpigmented (as in *N. paradoxa*); h - homogeneous pigment distribution throughout the petal, with the same total amount of pigment and scattering parameter; s - symmetric pigment distribution, where the same amount of pigment is equally deposited in two layers, adaxially and abaxially, with in between the purely scattering layer of the first case. We considered for all three cases the two...
previously encountered scattering parameters of the unpigmented layer, $S_u^* = 0.1$ (Fig. 5a,c) and 0.2 (Fig. 5b,d).

For each of the three cases, the calculated adaxial and abaxial transmittance spectra are of course identical (Fig. 5a,b). The calculated adaxial ($R_{ad}$) and abaxial ($R_{ab}$) reflectance spectra are identical for both the homogeneous and symmetric case, and the spectral differences between the two cases are small. However, an asymmetric localization of pigment yields very different adaxial and abaxial reflectance spectra, and hence very different colors of both sides.

Figure 5: Transmittance and reflectance spectra of a few differently organized model flower petals. (a,b) Transmittance ($T$) and adaxial reflectance ($R_{ad}$) spectra. c, d Abaxial reflectance ($R_{ab}$) spectra. The spectra are calculated for two values of the scattering parameter of the unpigmented layer, $S_u^*$: 0.1 (a, c) and 0.2 (b, d). The three model petals had the same amount of pigment and scattering distributed asymmetrically (a), homogenously (h), or symmetrically in the adaxial and abaxial layer (s).
A scattering and absorbing layer stack model to interpret flower coloration

(Fig. 5c,d). Clearly, with pigment localized on only one side, the light reflected by that side is more saturated than when the pigment is distributed homogeneously or symmetrically (Fig. 5). This is because the asymmetrically located pigment is most efficiently used with illumination of the pigmented side: the light backscattered by the unpigmented layer traverses the pigmented layer twice. Pollinators are capable of detecting very small differences in floral spectra and are especially sensitive for the degree of saturation (Lunau 1990, Renoult et al. 2013, Rohde et al. 2013). Obviously, for flowers that will be visited by pollinators from only one side the most efficient strategy is an asymmetrical deposition of pigment.

In conclusion, the combined Kubelka-Munk-layer-stack model allows a heuristic quantitative understanding of flower coloration. It enables a quantitative analysis of the relative importance of pigmentation and scattering. The approach presented here will help us to understand how plants can optimize their coloration for attracting pollinators as well as to explain the functional causes as to why plants use various flower coloration strategies.

**Appendix**

**Kubelka-Munk theory of absorbing and scattering media**

The light flux in a flower was modelled by using the Kubelka-Munk theory for absorbing and scattering media (Kubelka and Munk 1931), which assumes a homogeneous, pigmented slab with thickness $d$, and with absorption coefficient $K$ and scattering coefficient $S$ for randomly propagating light (Fig. 6a). Light entering the medium will be partly absorbed and scattered, resulting in a diffuse forward propagating light flux $I$ and a backward propagating light flux $J$.

The change in these light fluxes in an infinitesimal layer with thickness $dx$ is described by:

$$I(x + dx) = I(x) - KI(x)dx - S I(x)dx + SJ(x)dx$$  \hspace{1cm} (1a)

$$J(x + dx) = J(x) - KJ(x)dx - SJ(x)dx + SI(x)dx$$  \hspace{1cm} (1b)

or,

$$\frac{dI}{dx} = -(K + S)I + SJ$$  \hspace{1cm} (2a)
\[ \frac{dJ}{dx} = -SI + (K + S)J \]  

(2b)

The general solution of the two coupled linear differential equations is, assuming a unit incident light flux, \( I_0 = 1 \) at \( x = 0 \), and a zero backward light flux \( J_d = 0 \) at \( x = d \):

\[
I(x) = \left\{ \left( a + b \right) \exp \left( c(d - x) \right) - \left( a - b \right) \exp \left( -c(d - x) \right) \right\} / N
\]

(3a)

\[
J(x) = \left\{ \exp \left( c(d - x) \right) - \exp \left( -c(d - x) \right) \right\} / N
\]

(3b)

with

\[
N = \left( a + b \right) \exp(cd) - \left( a - b \right) \exp(-cd)
\]

(3c)

and

\[
a = 1 + K/S, \ b = \sqrt{a^2 - 1}, \ c = bS
\]

(3d)

Normalizing all parameters to the total thickness \( d \), Eqs. 3a-d yield

\[
I(x^*) = \left\{ A^* \sinh B^*(1 - x^*) + B^* \cosh B^*(1 - x^*) \right\} / \left\{ A^* \sinh B^* + B^* \cosh B^* \right\}
\]

(4a)

\[
J(x^*) = S^* \sinh B^*(1 - x^*) / \left\{ A^* \sinh B^* + B^* \cosh B^* \right\}
\]

(4b)

where

\[
S^* = Sd, \ A^* = aS^*, \ B^* = bS^* = cd, \ x^* = x/d
\]

(4c)

As an example, Figs. 6b,c present the forward and backward light fluxes, calculated with Eqs. 4a-c, as a function of the normalized distance \( x^* \) for a number of values of the ratio of the absorption coefficient and scattering coefficient, \( r = K/S = 2^n \), with \( n \) varying between -4 and +4, assuming a scattering parameter \( S^* = 1 \). It follows from Eqs. 4a-c that the reflectance \( R = J_0 \) and the transmittance \( T = I_d \) are:

\[
R = \left( S^* \sinh B^* \right) / \left( A^* \sinh B^* + B^* \cosh B^* \right)
\]

(5a)

\[
T = B^* / \left( A^* \sinh B^* + B^* \cosh B^* \right)
\]

(5b)
A scattering and absorbing layer stack model to interpret flower coloration

**Figure 6:** (a) Diagram for the light flux in a homogeneous, but scattering medium in a plate with thickness $d$, used in Kubelka-Munk theory. $I$ is the light flux in the forward direction with $I_0$, the incident light. $J$ is the flux in the backward direction. (b) The forward light flux, $I$, in a homogeneous but absorbing and diffusively scattering medium, with thickness $d$, absorption coefficient $K$ and scattering coefficient $S$, presented as a function of the normalized depth $x^* = x/d$. In this example, a unit light flux enters the medium, the scattering parameter $S^* = Sd$ has the value $S^* = 1$, and the ratio of the absorption coefficient and scattering coefficient is $r = K/S = 2^n$, with $n$ varying between -4 and +4; in the absence of absorption $n = -\infty$; $K = 0$. (c) The backward light flux, $J$, associated with the forward light flux of (b).
From Eqs. 5a,b the scattering and absorption parameters can be derived (Yamada and Fujimura 1991):

\[ S^* = \ln \left\{ \frac{(1-(a-b)R)}{T} \right\} / b \quad (6a) \]

and

\[ K^* = (a-1)S^*, \quad (6b) \]

with

\[ a = \frac{1 + R^2 - T^2}{2R}, \quad b = \sqrt{a^2 - 1} \quad (6c) \]

Therefore, when the thickness \( d \) is known, the scattering and absorption coefficients, \( S \) and \( K \), can be obtained by measuring the reflectance and transmittance spectra.

The general Kubelka-Munk case has two extreme limits, namely no scattering \((S = 0)\) and no absorption \((K = 0)\). When \( S = 0 \), there is only a forward light flux, or \( J(x) = 0 \) throughout the medium. Then Eq. 2a yields \( I(x) = \exp(-Kx) \), the classical Lambert-Beer law. The absorbance (or optical density) of a layer with thickness \( d \) then is \( D = -\log_{10}(\exp(-Kd)) = 0.4343Kd = 0.4343K^* \), with \( Kd = K^* \).

When \( K = 0 \), Eqs. 2a and 2b yield

\[ \frac{dI}{dx} = \frac{dJ}{dx} = S(J-I) = \text{const} \quad (7) \]

Hence, with \( I_0 = 1 \) and \( J_d = 0 \), it follows that

\[ I(x) = Sx / (1 + Sd) \quad (8a) \]

\[ J(x) = S(d-x) / (1 + Sd) \quad (8b) \]

or, with Eq. 4c:

\[ I(x) = 1 - S^* x^* / (1 + S^*) \quad (9a) \]

\[ J(x) = S^* (1 - x^*) / (1 + S^*) \quad (9b) \]

The reflectance and transmittance of the slab then are

\[ R = S^* / (1 + S^*) \quad (10a) \]
A scattering and absorbing layer stack model to interpret flower coloration

\[ T = \frac{1}{1 + S^*} \]  

(10b)

For a non-absorbing medium, the scattering parameter thus follows directly from its reflectance

\[ S^* = \frac{S}{1 - R} \]  

(11)

and, when the thickness \( d \) is known, the scattering coefficient \( S = S^*/d \) is immediately obtained.

Reflectance and transmittance of a stack of layers

We consider a stack of \( n \) layers, where each layer \( i \) has a characteristic reflectance \( r_i \) and transmittance \( t_i \) for forward propagating light \( I_i \), and \( s_i \) and \( u_i \) for backward propagating light \( J_i \) (Fig. 7a,b). Hence

\[ I_{i+1} = t_i I_i + s_i J_{i+1} \]  

(12a)

\[ J_i = I_i + \sum_{j=1}^{i} \left(t_j I_j + s_j J_j\right) \]  

(12b)

\[ I_{i+1} = \sum_{j=i}^{n} \left(t_j I_j + s_j J_j\right) \]  

(12c)

\[ J_{i+1} = \sum_{j=i}^{n} \left(s_j I_j + u_j J_j\right) \]  

(12d)

\[ I_{n+1} = t_n I_n + s_n J_{n+1} \]  

(12e)

\[ J_{n+1} = \sum_{j=n}^{n} \left(s_j I_j + u_j J_j\right) \]  

(12f)

Figure 7: Light propagation in a stack of four layers as a model for the flower of \textit{N. paradoxa}. (a) The model flower consists of an upper surface (ups), a pigment layer (pig), an unpigmented layer (unp), and a lower surface (los). (b) Each layer in (a) (with number \( i = 1-4 \)) has characteristic reflectances \( r_i \) and \( s_i \) and transmittances \( t_i \) and \( u_i \), with forward incident and transmitted light fluxes \( I_i \) and \( I_{i+1} \) and backward incident and transmitted light fluxes \( J_i \) and \( J_{i+1} \). The forward and backward light fluxes between the layers are sums of transmitted and reflected components.
and \( J_i = u_i I_{i+1} + r_i I_i \) \( \quad (12b) \)

Eqs. 12a,b are equivalent to (see Yamada and Fujimura 1991)

\[
\begin{pmatrix}
I_{i+1} \\
J_{i+1}
\end{pmatrix} = M_i \begin{pmatrix}
I_i \\
J_j
\end{pmatrix}, \quad \text{with} \quad M_i = \frac{1}{u_i} \begin{bmatrix}
u_i t_i - r_i s_i & s_i \\
-r_i & 1
\end{bmatrix}
\] \( \quad (13) \)

Although in general the reflectance values \( r_i \) and \( s_i \) as well as transmittance values \( t_i \) and \( u_i \) may differ, we may assume that layers can be chosen so that \( s_i = r_i \) and \( u_i = t_i \). The layer transfer matrix then is

\[
M_i = \frac{1}{t_i} \begin{bmatrix}
t_i^2 - r_i^2 & r_i \\
-r_i & 1
\end{bmatrix}
\] \( \quad (14) \)

For a stack of \( n \) layers Eq. 13 yields

\[
\begin{pmatrix}
I_{n+1} \\
J_{n+1}
\end{pmatrix} = M_s \begin{pmatrix}
I_1 \\
J_1
\end{pmatrix},
\]

with \( M_s = M_n M_{n-1} \cdots M_1 = \prod_{i=1}^{n} M_{n+1-i} = \begin{bmatrix}m_{11} & m_{12} \\
m_{21} & m_{22}\end{bmatrix} \) \( \quad (15) \)

For illumination from above (the side of plate 1 in Fig. 7a), the stack transmittance is \( T_a = I_{n+1} / I_1 \) and the stack reflectance is \( R_a = J_1 / I_1 \). With \( J_{n+1} = 0 \) and \( \det(M) = \det(M) = 1 \) it then follows that \( T_a = 1 / m_{22} \) and \( R_a = -m_{21} / m_{22} \). For illumination from below, i.e., the side of plate \( n \), Eq. 15 also holds, because of reversibility of light rays, but now the stack transmittance is \( T_b = J_1 / J_{n+1} \) and the stack reflectance is \( R_b = I_{n+1} / J_{n+1} \). With \( I_1 = 0 \) it then follows that \( T_b = 1 / m_{22} \) and \( R_b = m_{12} / m_{22} \). In other words, the transmittances are the same for illumination from either side of a stack, \( T = T_a = T_b \), but the reflectances may be different.

The stack transfer matrix \( M_s \), defined by

\[
\begin{pmatrix}
T \\
0
\end{pmatrix} = M_s \begin{pmatrix}
1 \\
R_a
\end{pmatrix} \quad \text{or} \quad \begin{pmatrix}
R_b \\
1
\end{pmatrix} = M_s \begin{pmatrix}
0 \\
T
\end{pmatrix},
\] \( \quad (16) \)
can be determined by measuring the transmittances and reflectances, because

\[
M_s = \frac{1}{T} \begin{bmatrix} T^2 - R_a R_b & R_b \\ -R_a & 1 \end{bmatrix}.
\]  (17)

We note that this matrix has the same formal shape as that for a single layer (Eq. 14) when the reflectances for illumination from above and below are equal, \( R_a = R_b \). Finally, when the optical properties of a single layer with number \( j \) are unknown, its transfer matrix \( M_j \) can be derived from

\[
M_j = \prod_{i=j+1}^{n} M_i^{-1} M_j^{-1} \prod_{i=1}^{j-1} M_i^{-1}
\]  (18)

so that the transmittance and reflectance of layer \( j \) then can be obtained with \( i = j \) from Eq. 14.

As an alternative to the above formal analysis, a slightly more intuitive approach is outlined below. Eqs. 12a,b yields that the transmittance parameter of each layer is

\[
\tau_i = I_{i+1} / I_i = t_i / (1-s_i \rho_{i+1})
\]  (19a)

and the reflectance parameter is

\[
\rho_i = J_i / I_i = r_i + u_i \rho_{i+1} \tau_i
\]  (19b)

With \( s_i = r_i \) and \( u_i = t_i \)

\[
\rho_i = r_i + t_i \rho_{i+1} \tau_i
\]  (20a)

and

\[
\tau_i = t_i / (1-r_i \rho_{i+1})
\]  (20b)

From Eqs. 20a,b it follows that

\[
\rho_i = r_i + t_i^2 \rho_{i+1} / (1-r_i \rho_{i+1})
\]  (21a)
and equivalently that
\[ \rho_{i+1} = \frac{(\rho_i - r_i)}{1 + r_i(\rho_i - r_i)} \]  
(21b)

With light incident only from one side, \( J_{n+1} = 0 \), or, \( \rho_{n+1} = 0 \), so that, when the reflectance and transmittance values for all layers are known, the stack reflectance \( R_s = J_1/I_1 = \rho_1 \) is obtained by subsequently calculating \( \rho_i \) for \( i = n, n-1, \ldots, 2, 1 \). The transmittance \( T_s = I_{n+1}/I_1 = \prod_{i=1}^{n} \tau_i \) follows from Eq. 20b by subsequently calculating \( \tau_i \) for \( i = 1, 2, \ldots, n \).

For the special case of \( N. \) paradoxa, layers 1 and 4 are the surfaces of the adaxial and abaxial epidermis. Layers 2 and 3 are inhomogeneous and thus will scatter propagating light. Layer 3 is assumed to be unpigmented, and therefore the reflectance and transmittance values are determined by only the scattering coefficient, which will be about constant, that is, independent of the light wavelength. The reflectance and transmittance of layer 3 hence are described by Eqs. 10a,b. However, in the pigmented layer 2 the absorption and scattering coefficient, and thus its reflectance and transmittance, will be wavelength dependent.

We can estimate the reflectance and transmittance of layer 2 with the procedure outlined below. We therefore consider again a stack of \( n \) layers, but now the reflectance and transmittance of all layers are known except one, that with number \( j \). Then, with illumination from the side of layer 1, by measuring the stack reflectance \( R_s = \rho_j \), we can calculate \( \rho_j \) with \( i = 2, 3 \ldots j \) by using Eq. 21b with \( i = 1, 2, \ldots j-1 \). The other reflectance parameters \( \rho_i \) can be calculated by using Eq. 21a and \( \rho_{n+1} = 0 \), going from \( i = n, n-1, \ldots \) to \( i = j+1 \). Subsequently, with Eq. 20b we can calculate \( \tau_i \) for \( i = 1 \ldots j-1 \) and \( i = j+1 \ldots n \). By measuring the stack transmittance \( T_s \), we then can calculate
\[ \tau_j = \frac{T_s}{\prod_{i=1}^{j-1} \tau_i \prod_{i=j+1}^{n} \tau_i} \]

Having thus obtained the compound reflectance and transmittance parameters \( \rho_j \) and \( \tau_j \), we can derive the reflectance and transmittance of layer \( j \), \( r_j \) and \( t_j \), because Eqs. 20a,b are equivalent to
\[ t_j = \frac{\tau_j(1 - \rho_j r_j \tau_j^2)}{\left[1 - \rho_j^2 \tau_j^2 \right]} \]
(16a)
and
\[ r_j = \rho_j - t_j \rho_{j+1} \tau_j \]
(16b)
Finally, with \( r_j = R \) and \( t_j = T \) we derive from Eq. 6a-c the scattering and absorption parameters of layer \( j \), \( S^* \) and \( K^* \), and with the thickness \( d \) of layer \( j \), the scattering and absorption coefficients \( S = S^*/d \) and \( K = K^*/d \) are obtained.
