Chapter 6

Treatment outcome of two adjacent implant crowns in the aesthetic zone; a one-year prospective comparative study of different implant platform designs

This chapter is an edited version of the manuscript:

Tymstra N, Raghoebar GM, Vissink A, den Hartog L, Stellingsma C, Meijer HJA. Treatment outcome of two adjacent implant crowns in the aesthetic zone; a one-year prospective comparative study of different implant platform designs. Submitted
Abstract

**Purpose** The aim of this comparative randomized clinical trial was to evaluate the peri-implant tissues in patients with two adjacent implant crowns in the maxillary aesthetic zone, treated with two adjacent implants with a scalloped platform or with a flat platform.

**Materials and methods** 40 patients were randomly allocated to one of two study groups. 1) ‘Scalloped implant group’: 20 patients treated with two adjacent implants with a scalloped platform and 2) ‘flat implant group’: 20 patients treated with two adjacent implants with a flat platform. After a 3 months provisionalisation period, all implants were restored with ceramic restorations. Clinical and radiographic examinations were performed during a one-year follow-up period to assess hard and soft tissue changes.

**Results** No implants were lost during the one-year follow-up. The scalloped implant group showed significantly more marginal bone loss (scalloped; 2.7±1.4mm, flat; 0.9±0.8 mm) and more inter-implant bone crest loss (scalloped; 1.8±1.4, flat; 1.0±0.9 mm) than the flat implant group. There was no significant difference between the groups with regard to the papilla index, and patients’ satisfaction.

**Conclusion** From this study it is concluded that after one year of function there was more bone loss around scalloped implants than around flat implants. With regard to the papilla presence, there were no differences between the groups. With both applied implant designs, it’s difficult to establish predictable and harmonious aesthetic result, especially regarding the peri-implant mucosa. Considering the critical opinion of the professionals, patients were very satisfied with the aesthetic outcome of the adjacent implants irrespective of the applied treatment concept.
Chapter 6

Introduction

During the last years, the focus in implantology has shifted from implant survival to implant success. This change in focus is reflected in the fact that during these last years the articles on implant survival and implant osseointegration are complemented with articles evaluating implant success. Criteria for implant success in the aesthetic zone include the establishment of a soft tissue contour with an intact interproximal papilla and a gingival outline that is harmonious with the gingival silhouette of the adjacent healthy dentition (Choquet et al., 2001). Despite the abundance of surgical techniques currently available, creation of a predictable papilla approximal of a single-tooth implant and especially between two adjacent implants in particular remains a complex challenge (den Hartog et al., 2008; Kourkouta et al., 2009).

Whether interproximal papillae will develop next to single tooth implants is predominantly dependent on the level of the marginal bone and the attachment level of the neighbouring teeth (Grunder, 2000; Kan et al., 2003; Ryser et al., 2005). This also explains why creation of a papilla between adjacent implants is even more a challenge, as unlike approximal of single-tooth implants, a papilla between two adjacent implants is not supported by the marginal bone level of a neighbouring tooth. In addition, the bone condition in many of such cases is compromised too. Amongst others, because of the traumatic loss of the teeth and/or the ongoing resorption of this area, the characteristic interdental bone peak is usually missing. In addition, it is not uncommon that significant deficiencies of the horizontal or vertical hard tissues are present in this area and are in need of an augmentation procedure to allow for reliable implant placement at a location favourable for prosthodontic rehabilitation. In other words, placement of two adjacent implant-supported restorations in the aesthetic zone is still considered a treatment with many uncertainties whether a predictable harmonious result can be established (Tarnow et al., 2000; Kourkouta et al., 2009).

In an attempt to preserve the peri-implant hard and soft tissues and thereby making implant therapy in the aesthetic zone more predictable, several new implant designs were launched in recent years. One of these solutions is the scalloped implant, which was designed to keep or create the interproximal bony peaks that support the overlying soft tissues and thereby aiming for a preservation or creation of papillae. The proximal scallops of the implant follow the contour of the alveolar bone crest, which is lower on the facial and oral aspects but rises in the interproximal areas. The ultimate goal of the scalloped implant design is to minimise
the remodelling seen around implants, thus significantly improving the quality of survival by maintaining three-dimensional osseous and soft tissue contours (Wohrle, 2003). Articles reporting on scalloped implants show contradicting results. Some studies reported that the interproximal bone crest with a scalloped implant design could be preserved (McAllister, 2007; Noelken et al., 2007). Whereas Kan et al. (2007) observed that bone was not regularly maintained at the original levels around the scalloped implants. Moreover, Nowzari et al. (2006) observed bone loss around the scalloped implants that was more severe than bone loss associated with properly placed flat implant designs. Up to now, there are no clinical prospective comparative studies in the literature, evaluating the treatment outcome of adjacent scalloped implants in the aesthetic zone.

When implants are placed in the aesthetic zone, one of the primary outcome measures should be patient satisfaction. In the end, the patient has to be satisfied with the new implant crown. Several studies reported about the patient satisfaction regarding implant crowns (Levi et al., 2003; Vermylen et al., 2003). All these studies reported high levels of the patients’ satisfaction. However, if the professionals’ opinion was evaluated too, it was always less positive than the patients’ opinion (Chang et al., 1999; Palmer et al., 2007). Furthermore, there is a difference between patients and professionals regarding which factors patients and professionals consider to be of decisive importance for a good aesthetic outcome (Chang et al., 1999; Meijndert et al., 2007). As such, it is important to assess the overall satisfaction of the patient along with the evaluation of the peri-implant hard and soft tissues.

Therefore, the aim of this comparative randomized clinical trial was to assess clinical and radiographic parameters in patients with two adjacent implant crowns in the maxillary aesthetic zone, treated with either two adjacent implants with a scalloped platform (test group) or with a flat platform (control group).

Material and methods

Patient selection

The patients selected for this study had been referred to the Department of Oral and Maxillofacial Surgery (University Medical Center Groningen, University of Groningen, Groningen, the Netherlands) for implant based prosthodontic rehabilitation of two adjacent anterior maxillary teeth. All patients were 18 years or older and were included in the study only after providing
informed consent. The study was approved by the medical ethical committee of the University Medical Center Groningen. Patients were selected based on the following inclusion criteria:

- Missing or lost teeth were an incisor (central or lateral), a canine or a first premolar in the maxilla
- Teeth missing were adjacent
- Sufficient bone was available (if required, a bone augmentation procedure was performed at least four months before implant placement) for placement of two adjacent dental implants with the minimum dimensions of 10 x 3.5 mm
- Sufficient space in mesio-distal, bucco-lingual, and interocclusal dimensions was available for placement of two functional implant crowns with an anatomical design
- Implant site was free from infection

Exclusion criteria for this study were:

- Presence of medical and general contraindications for the surgical procedures
- Presence of an active and uncontrolled periodontal disease
- Bruxism
- Smoking
- A history of local radiotherapy to the head and neck region

The methodological design of the study was that of a comparative randomized clinical trial.

Surgical and prosthetic procedure

To rehabilitate the missing adjacent teeth, two treatment modalities were applied: 1) The ‘scalloped implant group’ (test group) consisting of 20 patients treated with two adjacent implants with a scalloped implant platform (NobelPerfect Groovy; Nobel Biocare AB, Göteborg, Sweden) and 2) the ‘flat implant group’ (control group) consisting of 20 patients treated with two adjacent implants with a flat implant platform (NobelReplace Groovy, Nobel Biocare AB, Göteborg, Sweden) (Figure 1). Treatment allocation was performed using a balancing procedure to provide for an equal distribution of patients over the treatment groups with regard to the tooth gap location and whether a preoperative augmentation was needed. Both types of implants used in this study were tapered and roughened to the top of the implants with a titanium oxide (TiUnite; Nobel Biocare AB, Göteborg, Sweden).

All patients were treated in the same department (Oral and Maxillofacial Surgery, University
Medical Center Groningen, University of Groningen, Groningen, the Netherlands) by one experienced oral-maxillofacial surgeon and two experienced prosthodontists. Preoperatively, diagnostic casts were made with a diagnostic arrangement representing the future implant crown in the ideal prosthetic position. Next, this ideal crown position was translated into a surgical template by fabricating a transparent acrylic resin template (Vertex Castapress; Vertex-Dental BV, Zeist, the Netherlands). The surgical guide was completed with a guide channel which was prepared in the template to aid in proper implant placement. The surgical template was tooth supported and mimicked the desired emergence profile of the future implant crown.

One day before implant placement, the patients began using a 0.2% chlorhexidine mouthwash.

Figure 1.
Illustration of the a) flat implant design and b) the scalloped implant design from a proximal and c) buccal point of view.
One hour before implant surgery patients started taking antibiotics (amoxicillin 500 mg, 3 times daily for seven days). Under local anaesthesia (Ultracaine D-S Forte; Aventis Pharma Deutschland GmbH, Frankfurt am Main, Germany) the implants were placed, according to the manufacturer instructions, guided by the surgical template. A mucoperiosteal full-thickness flap was raised, which provided a clear view on the (availability and quality of the) hard tissues of the surgical area. In coronal-apical position, the facial part of the platforms of both implant designs were placed 2-3 mm apical to the most apical portion of the surgical template. The implants were placed with a maximum of 45 Ncm torque. In the scalloped implant group, the interproximal peaks of the implants were aligned towards the interproximal bone, facing the adjacent teeth or adjacent implants. Alignment of the interproximal peaks of the adjacent implants followed the natural arch curvature instead of a straight line. Final rotational alignment of the scalloped implants was achieved by using the manual torque wrench (Nobel Biocare AB, Göteborg, Sweden).

When deemed necessary the osseous crest was recontoured or slightly overcontoured to require a 2-3 mm thick bone wall on the facial aspect of the implants. Furthermore, when the bone apposition area of the implants remained uncovered after proper positioning in coronal-apical direction, a local augmentation was performed. For the simultaneous augmentation procedures an autogenous bone graft, collected during drilling or harvested intra-orally was combined with Geistlich Bio-Oss® (Geistlich Bio-Oss®, spongiosa granules (0.25-1.0 mm), Geistlich Pharma AG, Wolhusen, Switzerland) and overlaid with a Geistlich Bio-Gide® resorbable bilayer membrane (Geistlich Bio-Gide®, Geistlich Pharma AG, Wolhusen, Switzerland). The wound was closed primarily with sutures (Ethilon 5-0; Johnson & Johnson Health Care, Piscataway, NJ). For pain control, 600-mg ibuprofen (Brufen Bruis 600; Abott BV, Hoofddorp, the Netherlands) was prescribed, to be taken 3 times daily if needed. Two weeks following implant surgery, the sutures were removed.

Three months after implant placement, the implants were uncovered and a healing abutment (scalloped implant group; NobelPerfect healing abutment and flat implant group; NobelReplace healing abutment, Nobel Biocare AB, Göteborg, Sweden) was placed.

Two weeks later, an open tray impression was made at the implant level using a custom acrylic resin impression tray (Lightplast base plates; Dreve Dentamid GmbH, Unna, Germany) and a polyether impression material (Impregum Penta; 3M ESPE, St. Paul, MN). In the dental
Laboratory, screw-retained provisional crowns were fabricated, consisting of a temporary abutment (scalloped implant group: temporary abutment titanium NobelPerfect or flat implant group: NobelReplace temporary abutment Engaging; Nobel Biocare AB, Göteborg, Sweden) against which veneering composite (Solidex; Shofu, Inc, Kyoto, Japan) was modelled. One week after the impression was made, the healing abutments were removed and the provisional crowns were placed and torqued to 32 Ncm. The provisional crowns were contoured so that the peri-implant soft tissue was optimally supported. Extra care was given to the interproximal areas; the interproximal papillae were given enough space to regenerate. For three months, the patients visited the prosthodontist once per month for examination. The most important objective during these appointments was the creation of an ideal emergence profile of the provisional crowns. When needed, the crowns were unscrewed and adjusted by removing or adding composite resin to create more space or more support for the peri-implant soft tissues. Three months later (6 months following implant placement, three months after abutment connection) another implant-level impression was made for the fabrication of the definitive crown. In the dental laboratory, a soft tissue cast was prepared. First, a waxing of the definitive crowns was made on temporary abutments (scalloped implant group: temporary abutment titanium NobelPerfect or flat implant group: NobelReplace Temporary Abutment Engaging; Nobel Biocare AB, Göteborg, Sweden). After that, the waxing was cut back to the desired form and scanned for fabrication of individual zirconia abutments (Procera; Nobel Biocare AB, Göteborg, Sweden). Since there were no individual zirconia abutments available for the NobelPerfect implants, an individual titanium abutment was fabricated, covered by a zirconia coping. If the screw access hole was located mid-palatinally, the porcelain was added directly to the abutment to create a screw-retained crown. The crowns were placed and the abutment screws were torqued to 32 Ncm. Finally, the screw holes were filled with a cotton pellet and composite resin (Clearfil AP-x; Kuraray Medical, Inc, Okayama, Japan). If the access hole was not located mid-palatinally, a full ceramic zirconia crown was fabricated separately. The screw-retained abutments were torqued to 32 Ncm and the crown was fastened on the abutment with Fuji Plus cement (GC, Alsip, IL).

Clinical examinations
Pre-operatively (Tpre), one month (T0) and one year (T1) after placement of the definitive
implant crowns, the soft tissues around the adjacent implants and their neighbouring teeth were clinically examined by assessing the following parameters:

- Papilla index according to Jemt (1997);
- Pocket probing depth: the depth of the sulcus was measured to the nearest millimetre at three locations around the implants and the neighbouring teeth (at the side of the neighbouring teeth, midbuccally and at the side of the adjacent implants).

Photographic examinations
Pre-operatively (Tpre), one month (T0) and one year (T1) after placement of the definitive implant crowns, clinical standardised photographs were taken from the adjacent implant crowns and the neighbouring teeth (Meijndert et al., 2004) (Figure 2 and 3). The photographs were analysed using computer software to perform linear measurements on the digital photographs. The known length of a periodontal probe, which was photographed together with the dentition, was used for calibration.

The level of the marginal gingiva was assessed to the nearest 0.1 mm by measuring 1) the vertical distance from the incisal edge of the crown to the tip of the papilla at the proximal side facing the neighbouring teeth and 2) at the proximal side facing the adjacent implants and 3) the vertical distance from the incisal edge to the marginal border of the gingiva assessed midbuccally.

Figure 2.

Figure 2.
Picture of a clinical situation of two adjacent scalloped implants at T1.
Radiographic examinations

Two weeks after implant placement (Tpost), one month (T0) and one year (T1) after placement of the definitive implant crowns, digital periapical radiographs were taken using a paralleling technique (Figure 4 and 5). A computer-assisted calibration was carried out in the horizontal plane and, if necessary, in the vertical plane for each radiograph. In the horizontal plane the known dimension of the diameter of the implant was used to calibrate the radiograph. When the implant was slightly angulated, the radiograph was also calibrated in the vertical plane by using the known distance of several threads as calibration. This calibration ensured a correct measurement (Sewerin, 1990). The radiographs were analysed using computer software to perform linear measurements on the digital radiographs. Measurements were excluded if one of the landmarks to be determined could not be confidently identified. In the vertical plane, the following linear measurements were assessed to the nearest 0.1 mm (Figure 6):

- For the scalloped implant group: the apical corners of the implant collar were used as a reference line (line a_{scal}) and for the flat implant group: the interface of the implant and the abutment was used as a reference line (line a_{fla}) from which all distances were measured;
- The first bone to implant level: the vertical distance between a and the first bone to implant level.

![Figure 4. Radiograph of two adjacent scalloped implants at T1.](image)

![Figure 5. Radiograph of two adjacent flat implants at T1.](image)
level, measured at the implant side facing the adjacent implant (MBI_i) and at the implant side facing the neighbouring tooth (MBI_t);

- The bone level of the neighbouring tooth: the vertical distance between a and the first bone to tooth level (MBT);
- The bone crest level: the vertical distance between a and the most coronal bone peak of the inter-implant bone crest (BC_i) and the most coronal bone peak of the bone crest between the implants and their neighbouring teeth (BC_t);
- In the horizontal plane the inter-implant distance: the distance between the two adjacent was measured at height of the implant neck of the two adjacent implants (HD_i).

The true marginal bone level for the scalloped implant group was calculated by combining the radiographic assessments with the known dimensions of the NobelPerfect implants (Nobelbiocare AB, Göteborg, Sweden): the actual proximal microgap of the scalloped implants was located at the top of the interproximal scallops. Therefore the true marginal bone level was calculated as the measured first bone to implant level plus the actual height of the scallops of the implant collar, which is 4.01 mm for the NobelPerfect regular platform implants and 3.64 mm for the NobelPerfect narrow platform implants.

All measurements were done twice and the mean value calculated. The error of the method used was reported 0.13±0.01 for the assessment of the radiographic marginal bone height (Meijndert et al., 2004). All radiographic assessments were performed by a single observer.

**Implant crown aesthetic index**

Aesthetic outcome by the professional was assessed using the Implant Crown Aesthetic Index as described by Meijer et al (2005). In this index nine items are judged, which have an influence on the aesthetic result. The items are based on the anatomic form, colour and surface characteristics of the restoration and on the anatomic form, colour and surface characteristics of the peri-implant soft tissues. The index was applied to both implants separately. To assess the overall score, the implant with the worst index score was used as score per patient.

**Patients’ satisfaction**

A subjective appreciation of the final result of the treatment was assessed with a modified patient questionnaire of the one used by Meijndert et al. (2007). The questionnaire comprised
an overall satisfaction score (range; 0-10), two questions concerning the implant-supported restoration and two questions concerning the peri-implant mucosa (possible score; 0-4).

**Statistical analysis**

Mean values and standard deviations were calculated for the pocket probing depth, change in marginal gingiva, marginal bone level and marginal bone changes. Differences between the groups were analysed using the independent T test. If the data violated the assumptions of a normal distribution, differences between the groups were analysed using the Mann-Whitney test. Frequency distribution of the papilla index, patient satisfaction and the aesthetic index were calculated. Differences between the groups were analysed using the Mann-Whitney test. With regard to the aesthetic index, differences between the outcomes of the crown and the mucosa were analysed using the Mann-Whitney test. In all statistical tests, a significance level of $\alpha = 0.05$ was chosen. Statistical analysis was performed using Statistical Package for the Social Sciences (SPSS, version 16.0 for Windows, SPSS Inc., Chicago, IL).

**Results**

**Patients**

Patient characteristics per group are listed in Table 1 showing an equal distribution of the balancing criteria between the two groups. At T1, one patient in the scalloped implant group had passed away and in the flat implant group one patient did not attend the one year evaluation. The latter patient had moved without leaving a new address.

Clinical and radiographic assessments

No implants had been lost at T1, resulting in a 100% survival rate in both groups. Pocket probing depth at the implants and the neighbouring teeth are given in Table 2 indicating that scalloped implants were accompanied with higher probing depths than flat implants. Marginal gingiva levels are shown in Table 3. During the period between T0 and T1 the marginal gingiva recession at the proximal side facing the adjacent implant and midbuccally was significantly larger around scalloped implants than around flat implants. During the period between Tpre and T1, the loss in marginal gingiva midbuccally of the neighbouring teeth was significantly higher in patients of the scalloped implant group than in patients of the flat implant group. Frequency distribution of the papilla index is given in Table 4. Differences between the two groups were not significant. Table 5 shows the results of the marginal bone changes and the marginal bone levels at T1. The marginal bone loss was significantly higher around scalloped implants with 2.7 mm at the approximal side facing the adjacent implant and 2.6 mm at the approximal side facing the

* No significant differences between the groups were observed.

** Score 0 = no papilla formation, Score 1 = less than half of the papilla is present, Score 2 = at least half of the papilla is present, Score 3 = papilla fills whole approximate space, Score 4 = abundance of papilla

Abbreviations: T0 = one month after placement of the definitive crown, T1 = twelve months after placement of the definitive crown.
adjacent tooth than around flat implants (0.9 mm for both approximal sides). The relatively high marginal bone loss around scalloped implants resulted in a significantly more apically from the microgap situated mean marginal bone level at T1 (3.7 mm from the microgap at the side facing the adjacent implant and 3.3 mm apical from the microgap at the side facing the adjacent teeth).

The mean horizontal distance between the two adjacent implants was 3.2±1.0 mm and 3.8±1.1 mm for the scalloped implant group and the flat implant group, respectively.

The results of the implant crown aesthetic index are depicted in Table 6. The overall score of the implant crown aesthetic index resulted in no significant differences between the groups. Patient satisfaction was very high. Results of the satisfaction questionnaire revealed a mean overall score of 8.3 and 8.8 for the scalloped implant group and the flat implant group, respectively (Table 7).

**Discussion**

There was more bone loss, deeper pockets and more marginal gingiva recession around scalloped implants than around flat implants. The inter-implant papilla showed in both groups compromised regeneration, with no significant differences between the groups. With both applied implant designs, it’s difficult to establish a predictable and acceptable aesthetic result with two adjacent implant crowns in the aesthetic zone. Nevertheless, patients were very satisfied with the aesthetic outcome.

The implant survival rate for both groups was 100% following one year of function, which is in agreement with the common opinion on implant survival rates in the aesthetic region (den Hartog et al., 2008). The results of this study are also comparable with the results of articles reporting on implants with the same titanium oxide surface (TiUnite) as used in the present study (Glauser et al., 2003; Vanden Bogaerde et al., 2005) and implants with a scalloped platform (Nowzari et al., 2006; Kan et al., 2007). A comparison with studies reporting on implant survival of adjacent implants could not be made because there were no articles reporting on survival rates.

The mean marginal bone loss around the implants during the period Tpost - T1 was significantly higher for the scalloped implant group than for the flat implant group. The marginal bone loss was 2.7 mm at the approximal side facing the adjacent implant and 2.6 mm at the approximal

† Significance for the difference between the two treatment groups.

Abbreviations: Tpost = post-implantation time, T0 = one month after placement of the definitive crown, T1 = 12 months after placement of the definitive crown. Scalloped = scalloped implant, Flat = flat implant group, NS = not significant.

Table 5. Mean (SD) bone change values (mm) during the evaluation period and bone level in mm at T1.
side facing the adjacent tooth for the scalloped implant group and 0.9 mm for both approximal sides of the flat implant group. The relatively high marginal bone loss around scalloped implants resulted in a mean marginal bone level at T1 of 3.7 mm apical from the microgap at the side facing the adjacent implant and 3.3 mm apical from the microgap at the side facing the adjacent teeth. This marginal bone loss even exceeds the criteria of success stated by (Albrektsson et al., 1986); proposing an average bone loss of a maximum of 1.5 mm in the first year after insertion and thereafter < 0.2 mm annual bone loss. The flat implant group does meet these criteria of success. Moreover, the mean marginal bone loss of the flat implant group are comparable to results of articles in literature reporting on the same implant system used in single-tooth replacement (Friberg et al., 2005; Fischer et al., 2009).

The marginal bone level around the scalloped implants seems less stable than the marginal bone level around flat implants. In the period between T0 and T1 (7 to 18 months after implant insertion), still a mean marginal bone loss of 0.5 mm at the proximal side facing the adjacent teeth and 0.4 mm at the proximal side facing the adjacent implants occurred around the scalloped implants in comparison to 0.1 mm at the proximal side facing the adjacent teeth and 0.0 mm at the proximal side facing the adjacent implant. It seems as if the marginal bone level does not follow the scalloped three-dimensional platform of the implant design, as it was meant to do. An explanation for the excessive bone loss around the scalloped implants might be that the lower lingual and facial part of the implant platform determine the marginal bone level around the implant. Furthermore, the mean inter-implant bone crest loss was higher if scalloped implants were applied. This is probably predominately the result of two factors. At first the higher mean marginal bone loss around the scalloped implants probably results in a larger horizontal component of the peri-implant bone loss. Secondly, the mean horizontal distance of 3.2 mm between adjacent scalloped implants was significantly smaller than the mean horizontal distance of 3.8 mm between adjacent flat implants. Moreover, there were more patients in the scalloped implant group with a horizontal distance smaller than 3 mm than in the flat implant group. This is partly due to the design of the narrow NobelPerfect platform implant, in this study placed at the position of the lateral incisor. The implant neck still has a diameter of 4.31 mm instead of 3.54 mm diameter of the narrow platform of the ReplaceSelect implant. An inter-implant horizontal distance smaller than 3 mm will result in larger vertical reduction of the inter-implant bone crest, due to overlap of the
resorption areas between the adjacent implant (Tarnow et al., 2000; Gastaldo et al., 2004). Papilla indices scores pointed towards a compromised papilla presence. There were no significant differences between the groups. In both groups the inter-implant papilla scored worse compared to papillae between an implant and a natural tooth with regard to the inter-implant papilla. As the soft-tissue follows the contour of the hard tissues, the reduced inter-implant bone crest height caused a compromised papilla formation. Next to the reduced bone crest height, between two adjacent implants only a soft tissue height of 3-4 mm should be expected instead of 5 mm soft-tissue height between an implant and a tooth (Gastaldo et al., 2004). Together, these two features predominantly cause the compromised papilla presence between two adjacent implants.

The mean pocket probing depths were deeper around scalloped implants than around flat implants. At T1, the mean pocket probing depths next to the scalloped implants ranged from 4.0 mm midbuccally to 5.3 mm at the proximal side facing the adjacent teeth. Whereas, around the flat implants the mean pocket probing depths at T1 ranged from 3.3 mm midbuccally to 3.8 at the proximal side facing the adjacent teeth. The results of the flat implant group are in agreement with results reported on single tooth replacements (Wennstrom et al., 2005). The studies published on scalloped implants did not report on pocket probing depth, therefore it was not possible to compare the results of the present study with the literature. The significantly deeper peri-implant pockets around the scalloped implants are most likely the result of the more apical situated marginal bone level around the scalloped implants. The bottom of the peri-implant pockets is determined predominantly by the marginal bone level, whereas the top of the peri-implant pockets is determined by the top of the marginal gingival level. The marginal gingiva is held up by the most coronal level of the underlying bone which is assessed in this study as the inter-implant bone crest level between two adjacent implants and the implant-tooth bone crest level between an implant and its adjacent tooth.

The changes in marginal gingiva level around the flat implants that occurred during the periods Tpre –T1 and T0-T1 were very small, indicating the soft tissues and their neighbouring teeth remain rather stable during the 18 months after implant insertion. These results correspond to the results of other studies reporting on single tooth replacement (Jemt & Lekholm, 2005; Meijndert et al., 2008). During the period between T0 and T1 marginal gingiva recessions were significantly larger around scalloped implants at the approximal side facing the adjacent
implant a midbuccally in comparison with flat implants. The marginal gingiva levels around scalloped implants seem less stable, but changes are still relatively small. During the period between Tpre and T1, the loss in marginal gingiva midbuccally of the neighbouring teeth was higher in patients of the scalloped implant group than in patients of the flat implant group. No logical explanation could be ascribed to this difference between the groups because the implant insertion procedure did not differ between the groups.

With regard to the overall outcomes of the implant crown aesthetic index, there were no differences between the groups. The implant mucosa was rated as significantly worse when compared to the implant crown. The relatively low scores of the implant mucosa are

predominantly caused by the large amount of gross deviations with regard to the position of the approximal papilla observed in both groups. Furthermore, the position of the labial gingiva and the colour and surface of the labial mucosa showed some major and several minor deviations, also contributing to the relatively low mucosa score. The compromised papilla presence was already observed and explained with the papilla index. Moreover, in case of adjacent missing teeth, the bone condition at start of treatment is often compromised, due to resorption the characteristic interdental bone peak is missing. Even more, in both groups in more than half of the patients the horizontal or vertical deficiencies were to the extent that an augmentation procedure was performed prior to implant surgery (Table 1). As a result, the mucosa had to undergo several traumatic surgeries. The compromised situation at start and the several traumatic surgeries also might contribute to the deviations found with regard to the position of the labial gingiva and the colour and surface of the labial mucosa. When the overall scores of the aesthetic index of this study was compared with the outcomes of a previous study reporting on single tooth replacement and also applying the aesthetic index (Meijndert et al., 2008), adjacent implant crowns give worse aesthetic outcomes than implant crowns single tooth replacements.

Patient satisfaction was very high, resulting in mean overall scores of 8.3 (range 0-10) for the scalloped implant group and 8.6 for the flat implant group, this difference was not

significant. In accordance with the professionals’ opinion, patients also rated their mucosa worse than their implant crowns. Although the professionals’ opinion was very critical, patient satisfaction was very high with in all cases an acceptable result. This difference in opinion is in agreement with earlier studies concerning single-tooth replacement (Chang et al., 1999; Palmer et al., 2007). A reason why the patients appreciated their aesthetics could be that they were informed of the consequences and risks of implant placement prior to treatment and accepted the limitations of the treatment. Additionally, in comparison to the condition of their dentition prior to treatment, the final result was probably very satisfactory to the patients’ opinion. Furthermore, factors often considered by professionals to be of significance for the aesthetic result of restorative therapy may not be of decisive importance for patient satisfaction (Chang et al., 1999).

Long-term research is needed to assess the stability of the peri-implant hard and soft-tissues of adjacent implants in the aesthetic zone. Furthermore, it would be interesting to assess the effects of other promising implant designs such as platform switching on peri-implant tissues around adjacent implant in the aesthetic zone by means of a randomized clinical trial.

Conclusions
From this study it is concluded that after one year of function there was more bone loss, deeper pockets and more marginal gingiva recession around scalloped implants than around flat implants. With regard to the papilla presence, there were no differences between patients treated with two adjacent scalloped implants or with two adjacent flat implants. With both applied implant designs, it is difficult to establish a predictable and acceptable aesthetic result, especially regarding the peri-implant mucosa, with two adjacent implant crowns in the aesthetic zone. Considering the critical opinion of the professionals, patients were very satisfied with the aesthetic outcome of the adjacent implants irrespective of the applied treatment concept.
