Abstract

We study the Gibbsian character of time-evolved planar rotor systems (that is, systems which have two-component, classical $XY$, spins) on $\mathbb{Z}^d$, $d \geq 2$, in the transient regime, evolving with stochastic dynamics and starting from an initial Gibbs measure $\nu$. We model the system with interacting Brownian diffusions $X = (X_i(t))_{t \geq 0, i \in \mathbb{Z}^d}$ moving on circles. We prove that for small times $t$ and arbitrary initial Gibbs measures $\nu$, or for long times and both high- or infinite-temperature initial measure and dynamics, the evolved measure $\nu_t$ stays Gibbsian. Furthermore, we show that for a low-temperature initial measure $\nu$ evolving under infinite-temperature dynamics there is a time interval $(t_0, t_1)$ such that $\nu_{t_1}$ fails to be Gibbsian for $d \geq 2$.

Keywords: Gibbs property; Non-Gibbsianness; Stochastic dynamics; XY-spins

1. Introduction

During a stochastic evolution of Gibbs measures for spin systems various things can happen. In [1] the authors considered Ising-spin systems starting from an initial Gibbs measure $\nu$ and evolving under a spin-flip dynamics (high-temperature Glauber dynamics) towards a reversible Gibbs measure $\mu \neq \nu$, both having a finite-range interaction. They show that in this transient regime the evolved measure $\nu_t = \nu S(t)$ stays Gibbsian if either $t$ is small, or both $\nu$ and $\mu$ are at high or infinite temperature. It can lose the Gibbs property after some time $t$ if the initial measure is at low temperature and zero or small magnetic field and $\mu$ is at high or infinite temperature.

The Gibbs measure property is also shown to be recovered after some time if the initial measure \( \nu \) has a non-zero magnetic field. In some sense the initial external field will be compensated by a dynamic field, causing a hidden phase transition which makes the evolved measure non-Gibbs. For large enough time when the dynamic field is too weak to do this, there is re-entrance into the Gibbsian regime again. Thus in that case the evolved measure is Gibbsian if the time is either small or large enough. Le Ny and Redig generalized in [2] the result for small times \( t \) to more general dynamics. They consider spin systems with spins in \( \{0, 1\}^{\mathbb{Z}^d} \) and prove that Gibbsianness stays conserved when the system evolves under a more general local stochastic dynamics such as Kawasaki or mixtures of Glauber and Kawasaki dynamics.

The case of an infinite-temperature dynamics leads to the question of whether an effective temperature can be defined [3] in the transient regime, or, in a different interpretation, how reliable noisy observations are; see e.g. [4,5] or [6,7]. The last type of questions lead to the study of so-called “hidden Markov fields”.

Another Gibbsian question of interest for discrete spins with discrete-time dynamics is the study of PCA’s (probabilistic cellular automata) in \( d \) dimensions. Their stationary measures are projections of space–time Gibbs measures for a Hamiltonian obtained by the PCA in \( d + 1 \) dimensions in the stationary case. In [8] the authors prove the converse direction that all translation invariant or periodic stationary measures correspond to Gibbs measures on space–time histories for the PCA on a space \( \mathbb{Z}^{d+1} \).

What is known about the situation for continuous spins? Deuschel in [9] and later Roelly, Zessin and coauthors investigated in [10,11] Gibbs measures of interacting diffusions indexed by lattice sites on \( \mathbb{Z}^d \). First Deuschel described the law \( Q^\nu \) of the entire infinite-dimensional unbounded process \( X = ((X_i(t))_{0 \leq t \leq 1, i \in \mathbb{Z}^d} \) as a space–time Gibbs measure with state space \( C([0, 1])^{\mathbb{Z}^d} \) when the initial distribution \( \nu \) is Gibbsian. Then Roelly, Zessin and coauthors showed a bijection between the set of initial Gibbs measures associated with an initial interaction on \( \mathbb{R}^{\mathbb{Z}^d} \) and the set of Gibbs measures on the path space describing the full dynamics; see [11].

In [12] Dereudre and Roelly considered a problem which is close to the one we study, namely the Gibbsianness in the transient regime for the time evolution of unbounded continuous spins under high-temperature dynamics with bounded interactions. They start with the Gibbs representation of \( Q^\nu \) on the path level and look at the projections at time \( t \) of the law \( Q^\nu \). Then they prove that if the initial measure obeys a strong uniqueness condition, then either for small times or if the dynamical interaction is weak enough, Gibbsianness propagates for bounded initial and dynamical interaction. That means that the time-evolved measure is again a Gibbs measure for continuous spins and an absolutely summable interaction. Another case of unbounded continuous spins was treated by Külske and Redig in [13] where the authors also consider the time evolution of continuous unbounded spin models under infinite-temperature dynamics and unbounded interaction (as compared to Roelly and Dereudre who consider a bounded one). They prove that (similar to the result of [1] for discrete spins) for continuous unbounded spins the time-evolved measure stays Gibbsian for small times but loses this property for \( t \) large if the initial measure is a low-temperature measure. In contrast to the Ising-spin situation the Gibbsian property cannot be recovered again. The initial Gibbs measure is Gibbsian for a Hamiltonian with a quadratic nearest neighbour interaction and an a priori single-site double-well potential that has a specific form. This particular form of the interaction term allows an explicit analysis. Their definition of a Gibbsian measure is weaker than the DLR definition imposing an absolutely summability condition on the interaction like [12]. In the case of unbounded spins it seems more natural to weaken the assumptions on the interaction since absolutely summability does not even allow Gaussian fields.
The fact that the Gibbs property cannot be recovered again is due to the unboundedness of the spins and the interactions, but it has not to do with the continuity or discreteness of the spins.

The proof of non-Gibbsianness for continuous spins becomes somewhat simpler, compared to the discrete case, as the finding of a “bad” configuration, corresponding to a particular value of the dynamical field opposing the initial field, can be done by directly interpolating at the level of configurations (one can continuously change a configuration), whereas in the discrete models, drawing configurations from a measure with a continuously varying parameter leads to a technically more complicated problem of systems in external random fields.

In this paper we consider continuous but compact spins living on a circle \( S^1 \) (called either planar rotors or classical XY spins). After introducing the general set-up and some background in Section 2, we are ready to prove our results. We investigate the Gibbsian property of the system first, in Section 3.1, for small times \( t \) and arbitrary initial Gibbs measures \( \nu \) under different dynamics and then for small inverse initial temperature and arbitrary times. The purpose of Section 3.2 will be to show that the time-evolved measure \( \nu^t \) is Gibbsian for small \( t \) under infinite-or high-temperature dynamics and arbitrary-temperature initial Gibbs measure, and for any \( t \) for high- or infinite-temperature dynamics starting in a high- or infinite-temperature initial measure. We closely follow and in our case can simplify the approach of [12]. Although their approach was developed for unbounded spins, it seems especially appropriate to apply it to bounded spins, as in that case the notion of Gibbsianness for bounded interactions (quasilocality) is particularly natural as a notion of “reasonable” interactions.

Like in their approach we will get the time-evolved measure from projecting the path-space measure \( Q^\nu \) at time \( t \). The use of space–time cluster expansions in the study of non-Gibbsianness for Ising models in these regimes was developed and applied in [14,1]. In Section 4 we prove that the Gibbs property will be lost after some time \( t \) for a low-temperature initial measure and infinite-temperature dynamics, somewhat similarly to the situation in [13], for the classical nearest neighbour plane rotor for \( d = 2 \) with zero external initial field. This may seem slightly surprising, since the (translation invariant) Gibbs measure is unique at all temperatures (and in all homogeneous external fields). Thus, in contrast to the Ising case, finding a constraint which leads to a phase transition for the associated dynamical field is not immediate. As mentioned before, in our opinion the advantage of working with compact spins, besides the technical simplifications, is that the notion of Gibbsianness for a “reasonable” class of interactions is much less ambiguous. See e.g. the discussion in [15]. Closely related results have been obtained by Külske and Opoku [16] via a different approach using Dobrushin uniqueness techniques. The authors investigate short-time behaviour of spins moving on \( S^{N-1} \) and evolving with infinite-temperature dynamics. Moreover, in their more recent [17] they provide an analysis of the mean-field version of the problem, obtaining a quite complete picture.

2. General framework

We introduce some definitions and notation. The state space of one continuous spin is the circle, \( S^1 \). We identify the circle with the interval \([0, 2\pi)\) where 0 and \( 2\pi \) are considered to be the same points. Thus the configuration space \( \Omega \) of all spins is isomorphic to \([0, 2\pi)^{\mathbb{Z}^d}\). We endow \( \Omega \) with the product topology and natural product measure \( \nu_0(dx) = \bigotimes_{i \in \mathbb{Z}^d} \nu_0(dx_i) \).

In our case we take \( \nu_0(dx_i) = \frac{1}{2\pi}dx_i \). An interaction \( \varphi \) is a collection of \( \mathcal{F}_A \)-measurable functions \( \varphi_A \) from \((0, 2\pi)^A\) to \( \mathbb{R} \) where \( A \subset \mathbb{Z}^d \) is finite. \( \mathcal{F}_A \) is the \( \sigma \)-algebra generated by the canonical projection on \([0, 2\pi)^A\). The interaction \( \varphi \) is said to be of finite range if there exists an \( r > 0 \) s.t. \( \text{diam}(A) > r \) implies \( \varphi_A \equiv 0 \) and it is called absolutely summable if for all \( i \),
\[ \sum_{A \ni i} \| \varphi_A \|_{\infty} < \infty. \] We call \( \mu \) a **Gibbs measure** associated with a reference measure \( \nu_0 \) and interaction \( \varphi \) if the series \( H^\varphi_A = \sum_{A \ni i} \varphi_A \) converges pointwise (\( \varphi \) is absolutely summable) and \( \mu \) satisfies the DLR equations for all \( i \):

\[
\mu(dx_i | x_j, j \neq i) = \frac{1}{Z_i} \exp \left( -H^\varphi_i(x) \right) \nu_0(dx_i),
\]

where the normalization constant \( Z_i = \frac{1}{2\pi} \int_0^{2\pi} \exp(-H^\varphi_i(x)) \, dx \) is the partition function. We omit the inverse temperature \( \beta \) here, because in this section we deal with arbitrary initial inverse temperature. The set of all Gibbs measures associated with \( \varphi \) and \( \nu_0 \) is denoted by \( \mathcal{G}(\varphi, \nu_0) \) (or \( \mathcal{G}_\beta(\varphi, \nu_0) \) if we want to make the \( \beta \) dependence clear).

Furthermore we say an interaction \( \varphi \) satisfies a high-temperature Dobrushin condition ([12] call it a strong Dobrushin condition), if it is absolutely summable and

\[
\sup_{i \in \mathbb{Z}^d} \sum_{A \ni i} (|A| - 1) \sup_{x,y} |\varphi_A(x) - \varphi_A(y)| < 2. \tag{1}
\]

We will also refer to such an interaction as a **high-temperature interaction** and use the fact that if an interaction satisfies the condition above it follows that \( |\mathcal{G}(\varphi, \nu_0)| = 1 \); see e.g. [18].

Now, instead of working with Gibbs measures on \([0, 2\pi]^\mathbb{Z}^d\), we will first investigate Gibbs measures as space–time measures on the path space \( \hat{\Omega} = C([0, 2\pi])^\mathbb{Z}^d \). In [9] Deuschel introduced and described infinite-dimensional diffusions as Gibbs measures on the path space \( C([0, 1])^\mathbb{Z}^d \) when the initial distribution is Gibbsian. This approach was later generalized by [11] who showed that there exists a one-to-one correspondence between the set of initial Gibbs measures and the set of path-space measures \( Q^\nu \).

More precisely, let \( X = (X_i(t))_{t \geq 0, i \in \mathbb{Z}^d} \) be the solution of the following system of stochastic differential equations (SDE’s):

\[
\begin{align*}
\text{d}X_i(t) &= -\nabla_i \frac{1}{2} H^\varphi_i(X(t)) \, dt + dB_i^\odot(t), & t > 0, & i \in \mathbb{Z}^d \\
X(0) &\simeq \nu, & t = 0
\end{align*}
\tag{2}
\]

where \( \nu \) will be the initial Gibbs measure, \( \nu \in \mathcal{G}(\varphi, \nu_0) \), associated with some initial interaction \( \tilde{\varphi} \) which is supposed to be of finite range and at least \( C^2 \). \( B_i^\odot = (B_i^\odot(t))_{t \geq 0, i \in \mathbb{Z}^d} \) denotes a collection of independent Brownian motions on the circle at each lattice site \( i \). \( \nabla_i \) is a differential operator on the circle at lattice site \( i \) (equal to \( \frac{d}{d\theta_i} \)). In other words, the system at time 0 starts in a Gibbs distribution \( \nu \) and evolves according to a Brownian motion on the circle with some drift. Basically \( X_i(t) \) describes the position of the rotor spin at site \( i \) at time \( t \); it takes values in \( X_i(t)(\omega) \in [0, 2\pi] \) for every event \( \omega \). We refer the reader to [19] for a general overview of stochastic differential equations and to [20] for an overview of SDE’s on manifolds.

The interaction part of the stochastic dynamics of this process is hidden in the drift term of the SDE, namely in the gradient of the Hamiltonian \( H^\varphi \). The underlying dynamical interaction \( \varphi \) is also assumed to be of finite range and at least \( C^2 \). The Gibbs measures for it are transient and reversible. We will refer to different temperatures for the dynamics. What we mean by that is the following: Let the Gibbs measure \( \nu \) converge towards a reversible Gibbs measure \( \mu \). Then we say the dynamics is low, high or infinite temperature if the corresponding infinite-time measure \( \mu \) is a low-, high- or infinite-temperature Gibbs measure. Since the spins are compact, this implies that the derivatives are automatically bounded. The assumptions on \( \nu \) and \( \varphi \) provide the existence of a strong Markovian solution \( X \) of the above system (2). Let furthermore \( Q^\nu \) denote the law of the solution \( X \) on \( \hat{\Omega} \) with initial distribution \( \nu \).
We first note that the initial Gibbs measure \( \nu \) is a mixture of extremal Gibbs measures from the set \( \mathcal{G}(\hat{\varphi}, \nu_0) \); see also the representation theorem (Theorem 7.12 and 7.26 in [18]). Note that in general the mixture of \( Q^x \) under a measure \( \eta \) is given by \( Q^n = \int Q^x \eta(dx) \). This means that if \( \mu \) is an extremal element of \( \mathcal{G}(\varphi, \nu_0) \), then there exists a \( y \in [0, 2\pi)^\mathbb{Z}^d \) such that

\[
\mu = \lim_{A \to \mathbb{Z}^d} \mu_{A,y} \otimes \delta_{y,\Lambda^c}
\]

where \( \mu_{A,y}(dx) = \frac{1}{Z_{A,y}} \exp(-H^\varphi_{A\setminus y}(x, y)) \nu_0^{\otimes A}(dx_A) \) is the finite-volume Gibbs measure with fixed boundary condition \( y \), where

\[
H^\varphi_{A\setminus y}(x, y) = \sum_{A \cap A \neq \emptyset} \varphi_A(x_A y_{A^c}).
\]

Let first \( \nu \in \mathcal{G}(\hat{\varphi}, \nu_0) \) be extremal and let \( (\nu_{A,y})_A \) denote the approximating sequence as in (3). Then we have

\[
\nu_{A,y}(dx_A) = \frac{1}{Z_{A,y}} \exp \left(-\tilde{H}^\hat{\varphi}_{A\setminus y}(x, y)\right) \nu_0^{\otimes A}(dx_A).
\]

The tilde in \( \tilde{H}^\hat{\varphi} \) and \( \hat{\varphi} \) will always refer to the Hamiltonian or the interaction belonging to the initial distribution \( \nu \). Let us denote the set of all Gibbs measures which are obtained as weak limit points of finite-volume measure by \( \mathcal{G}_0(\hat{\varphi}, \nu_0) \) and remark that \( \mathcal{G}_0(\hat{\varphi}, \nu_0) \subset \mathcal{G}(\hat{\varphi}, \nu_0) \).

We define the \( i \)-decoupled initial measure \( \nu_{A,y}^i \) as

\[
\nu_{A,y}^i(dx_A) = \frac{1}{Z_{A,i}^y} \exp \left(-\tilde{H}^\hat{\varphi}_{A\setminus i}(x, y)\right) \frac{1}{(2\pi)^{|A|-1}} dx_{A \setminus i} \frac{1}{2\pi} dx_i
\]

\[
= Z_{A,i}^y \exp \left(\tilde{H}^\hat{\varphi}_i(x_A, y_{A^c})\right) \nu_{A,y}(dx_A).
\]

The decoupled Hamiltonian leaves out of the summation all sets containing site \( i \).

We notice that \( \nu_{A,y}^i \otimes \delta_{y,\Lambda^c} \) converges in \( \Lambda \) towards a measure \( \nu^i \) on \([0, 2\pi)^\mathbb{Z}^d \) with the following properties:

- \( \nu \ll \nu^i \) (absolutely continuous) and
- \( \nu(dx) = \frac{1}{Z^i} \exp(-\tilde{H}^\hat{\varphi}_i(x)) \nu^i(dx) \).

Let us write down the finite-dimensional \( i \)-decoupled dynamics:

\[
\begin{align*}
\frac{dX_i(t)}{dt} &= -\nabla_j H^\varphi_j(X(t)) dt + dB_j^\odot(t), & j \in \Lambda, j \neq i, & t > 0 \\
\frac{dX_i(t)}{dt} &= dB_i^\odot(t), & t > 0.
\end{align*}
\]

that is at lattice site \( i \) we put a Brownian motion \( B_i^\odot \) and the dynamics on the other lattice sites depend on all spins \( j \) which are not equal to \( i \). In the “decoupled regime” we start with an \( i \)-decoupled measure and evolve with \( i \)-decoupled dynamics. We denote by \( Q_{A}^{x,A} \) (resp. \( Q_{A,i}^{x,A} \)) the law of the solution of the (resp. \( i \)-decoupled) system of the finite system on \( \Lambda \) with fixed initial condition \( x_A \).

Moreover, the measures

\[
\lim_{A \to \mathbb{Z}^d} \nu_{A,y}^i \quad \text{resp.} \quad \lim_{A \to \mathbb{Z}^d} \nu_{A,y}^{i,i} = \nu^i, \nu^{i,i}
\]

converge in a weak sense. Here also no difficulties arise because of compactness of the spins.
If $t$ is large we, like [12], divide the dynamical interaction into two parts, $U + \beta \varphi$. $U$ is the self-interaction, which is a single-site term, and $\varphi$ is the interaction proper, while $\beta$ will serve as a small parameter. The term $U$ can also be viewed as the single-site drift term of the Brownian motions moving on the circle. The system will be defined as follows:

$$\begin{align*}
\{dX_i(t) &= -\frac{1}{2} U'(X_i(t)) dt - \frac{\beta}{2} \nabla_i H_i^\varphi(X(t)) dt + dB_i^\circ(t), \quad i \in \mathbb{Z}^d, \quad t > 0 \\
X(0) &\simeq \nu, \quad t = 0
\end{align*}$$

and for $\beta = 0$

$$\begin{align*}
\{dX_i(t) &= -\frac{1}{2} U'(X_i(t)) dt + dB_i^\circ(t), \quad i \in \mathbb{Z}^d, \quad t > 0 \\
X(0) &\simeq \nu, \quad t = 0.
\end{align*}$$

For long times the role of the inverse temperature $\beta$ will be important, so we include it in the definition of the process. We denote in the same spirit as before by $Q^\beta_0$ the law of the solution of (6) and by $Q^\nu_0$ the law of the solution of (7). We call $S$, the space $[0, 2\pi)^{\mathbb{Z}^d \times \{0,1\}}$, the bi-space. It will represent a double-layer system, to treat the distribution at time 0 and at time $t$ simultaneously. The joint distribution on the bi-space will be denoted by $Q^\nu_\beta = Q^\nu_0 \circ (X(0), X(t))^{-1}$. So we project the path-space measure $Q^\nu$ at times 0 and $t$.

We will use the following proposition to detect Gibbsianness of the evolved measure $\nu^t$.

**Proposition 2.1.** The following statements are equivalent:

1. $\mu$ is a Gibbs measure.
2. For all configurations $\eta$ and finite $\Lambda \subset \mathbb{Z}^d$ the measure $\mu$ admits a continuous and strictly positive version of its conditional probabilities.
3. $\mu$ admits a continuous version of the Radon–Nikodým derivatives $\frac{d\mu^i}{d\mu}$ for all $i \in \mathbb{Z}^d$ in the product topology.

A proof can be found in e.g. [21] and for continuous spins [18]. Indeed, as an informal explanation, the Radon–Nikodým derivative between the original and the decoupled measure is the exponent of the relative energy (the energy difference between the formally defined Hamiltonians of the original and the decoupled measures). If one is continuous, so is the other, and such energy differences are precisely the expressions occurring in the DLR equations. To determine whether a measure is Gibbs or not we will mainly use the third item. For the failure of Gibbsianness we will use the necessary and sufficient condition of finding a point of essential discontinuity of (every version of) the conditional probabilities of $\mu$, i.e. a so-called “bad configuration”. It is defined as follows.

**Definition 2.1.** A configuration $\xi$ is called **bad** for a probability measure $\mu$ if there exists $\varepsilon > 0$ and $i \in \mathbb{Z}^d$ such that for all $\Lambda$ there exists $\Gamma \supset \Lambda$ and configurations $\xi, \eta$ such that

$$|\mu_\Gamma(X_i | \xi_{\Lambda \setminus \{i\}} \eta_{\Gamma \setminus \Lambda}) - \mu_\Gamma(X_i | \xi_{\Lambda \setminus \{i\}} \xi_{\Gamma \setminus \Lambda})| > \varepsilon.$$

**3. Conservation of Gibbssianess**

**3.1. Small times**

Let the dynamical interaction $\varphi$ be of finite range and for every $\Lambda \subset \mathbb{Z}^d$ finite, let $\varphi_\Lambda$ be $C^2([0, 2\pi)^{\mathbb{Z}^d \setminus \Lambda})$. Denote by $H_i^\varphi$ the associated Hamiltonian function ($H_i^\varphi = \sum_{A: \Lambda \setminus \{i\} \neq \emptyset} \varphi_\Lambda$). We
consider now the process \( X = (X_i(t))_{t \geq 0, i \in \mathbb{Z}^d} \) defined by
\[
\begin{align*}
\left\{ \begin{array}{l}
\d X_i(t) = -\nabla_i \frac{1}{2} H_i^\psi (X(t))dt + dB_i^\phi(t), \quad i \in \mathbb{Z}^d, \quad t > 0 \\
X(0) \sim \nu, \quad t = 0.
\end{array} \right.
\end{align*}
\] (8)
where \( \nu \in G(\tilde{\phi}, \frac{1}{2\pi}dx) \) with \( \tilde{\phi} \) also of finite range and \( C^2 \). In particular since the spins are compact, \( \tilde{\phi} \) and \( \phi \) are also Lipschitz continuous. Conservation of Gibbianss for small times does not need any constraints on either the initial or the dynamical temperature, so we will not specify them. Then we have the following theorem:

**Theorem 3.1.** Let \( Q^\nu \) be the law of the solution \( X \) of the system (8). Let \( \nu \in G(\tilde{\phi}, \frac{1}{2\pi}dx) \) and let \( \phi \) satisfy the conditions above. Then there exists a time \( t_0(\phi, \tilde{\phi}) > 0 \) s.t. for all \( t \leq t_0 \) there exists an absolutely summable interaction \( \phi^t \) for which \( \{\nu^t = Q^\nu \circ X(t)^{-1} : \nu \in G(\tilde{\phi}, \frac{1}{2\pi}dx)\} \subset G(\phi^t, \frac{1}{2\pi}dx) \). The evolved interaction \( \phi^t \) depends only on the time \( t \), the initial interaction \( \tilde{\phi} \) and the dynamical interaction \( \phi \).

**Proof.** The proof follows basically that of [12]. We will show the scheme and give some explicit steps of their calculation. The main difference from [12] is in the assumptions on \( \tilde{\phi}, \phi \), the support of the initial measure \( \nu \) and the definition of the state space \( \Omega \) of the spins.

Since our spin space is compact we don’t need to impose boundedness conditions on the initial and dynamical interaction because these are automatically satisfied. Similarly, there is no problem in requiring Lipschitz continuity. Moreover the authors of [12] have to restrict themselves to supports of \( \nu \) which are included in \( l^1(\gamma) \) with \( \gamma = (e^{-\alpha|i|^2})_{i \in \mathbb{Z}^d} \) and \( \alpha > 0 \), which we don’t need to. For them it is needed to control the unbounded spins and ensure the weak convergence of \( \nu^t_A \) towards \( \nu^t \).

Our scheme, following [12], will be as follows.

To identify \( \nu^t \) as being a Gibbs measure for small times we want to use Proposition 2.1. Therefore we need to know what the Radon–Nikodým derivative, \( \frac{d\nu^t}{d\nu^t_A}(x) \), looks like for every \( t \) and \( i \). (We will prove the theorem for \( \nu \) being an extremal Gibbs measure.) Therefore we first compute \( \frac{d\nu^t}{d\nu^t_A}(x_A) \), the Radon–Nikodým derivative of the projected law of the finite-dimensional system in \( A \subset \mathbb{Z}^d \) at time \( t \) and some boundary condition \( y_A \) outside \( A \). Then using cluster expansion techniques and the weak convergence (5) we will be able to demonstrate that for \( t \) small, this derivative is continuous and behaves nicely. Next we can use the Kotecký–Preiss criterion, see [22], to deduce that this expansion converges, uniformly in \( A, x \) and the boundary condition \( y \). For \( A \) going to infinity this RN derivative approaches a continuous function. That will be enough to deduce the existence of an absolutely summable interaction \( \phi^t \) for which \( \nu^t \) is Gibbs if \( t \) is small.

Let us give now some steps of the calculation. In the following we fix a boundary condition \( y_A \) and compare the time-evolved finite-dimensional distribution \( \nu^t_{A,y} \) with the \( i \)-decoupled one \( \nu^t_{i,A,y} \). By some algebraic manipulation one gets for the Radon–Nikodým derivative \( \frac{d\nu^t_{i,A,y}}{d\nu^t_{A,y}}(x_A) \) that it has the following form.

**Lemma 3.1.** Let \( t > 0, A \subset \mathbb{Z}^d \) and \( i \in A \); then we have
\[
\frac{d\nu^t_{i,A,y}}{d\nu^t_{A,y}}(x_A) = \exp \left( -\tilde{H}_i^\psi (x_A, y_A) \right) \frac{\mathbb{E}^t_{Q^\phi_A} \left( \exp \left( f_{A,y}(X_A(t)) - f_{A,y}(x_A) \right) \right)}{\mathbb{E}^t_{Q^\phi_A} \left( \exp \left( f_{A\setminus i,y}(X_A(t)) - f_{A\setminus i,y}(x_A) \right) \right)}
\]
where
\[ f_{A,y}(x) = H^\varphi_{A,y}(x_A) - \mathcal{H}^\varphi_{A,c(x,y)}. \]

The proof is a straightforward computation.

The expression \( \mathcal{E}_{Q^x_A} \) means the expectation with respect to the measure \( Q^x_A \). Let us remark that for \( t \) small \( f_{A,y}(\tilde{X}_A)(t) - f_{A,y}(\tilde{X}_A) \) will turn out to be close to 0. We fix the time \( t \) and use Girsanov’s theorem and write the measures \( Q^x_A \) and the decoupled one \( Q^x_{A,i} \) in terms of densities w.r.t. the product \( \bigotimes_{j \in A} \rho^{\varphi,x_j} \). The terms \( \rho^{\varphi,x_j} \) denote the “Wiener measure on the circle” with initial condition \( x_j \). In other words, we want to find a function \( F^t_A \) such that

\[ Q^{x_A}_{A,y}(dX_A) = F^t_A(X_A) \bigotimes_{j \in A} \rho^{\varphi,x_j}(dX_j). \]

Girsanov’s theorem gives us the following form of \( F^t_A \):

\[
F^t_A(X_A) := \exp \left( \sum_{i \in A} \left( \int_0^t - \frac{1}{2} \left( \frac{d}{dx_i} H^\varphi_{i,A}(X_A(s)) \right) dX_i(s) - \frac{1}{8} \int_0^t \left( \frac{d}{dx_i} H^\varphi_{i,A} \right)^2 (X_A(s)) ds \right) \right).
\]

In [12] the authors use the classical Girsanov theorem, see e.g. [23], for the standard Wiener measure. For our particular diffusion, which is a diffusion on a circle, or more generally on a compact Riemannian manifold, we use a corresponding “Girsanov theorem” for Brownian motion on a compact manifold, see [24], which in the end gives the same expression for \( F \) as the classical one.

Using Itô’s formula, we can write the function \( F^t_A(X_A) \) as

\[
F^t_A(X_A) = \exp \left( -\frac{1}{2} H^\varphi_{A,y}(X_A(t)) + \frac{1}{2} H^\varphi_{A,y}(X_A(0)) \right) \times \exp \left( \sum_{i \in A} \int_0^t \left[ \frac{1}{4} \left( \frac{d^2}{dx_i^2} H^\varphi_{A,y} \right) - \frac{1}{8} \left( \frac{d}{dx_i} H^\varphi_{A,y} \right)^2 \right] (X_A(s)) ds \right)
\]

\[
=: \exp \left( -\sum_{A \subset A'} \varphi_A(X_A(t)) \right)
\]

with

\[
\varphi^{\varphi,i}_A(X_A) := \frac{1}{2} \varphi_A(X_A(t)) - \frac{1}{2} \varphi_A(X_A(0))
\]

\[
- \int_0^t \left( \frac{1}{4} \sum_{j \in A} \frac{d^2}{dx_j} \varphi_A(X_A(s)) - \frac{1}{8} \sum_{B \subset C = A \setminus \{i\}} \sum_{j \in B \cap C} \frac{d}{dx_j} \varphi_B(X_A(s)) \frac{d}{dx_j} \varphi_C(X_A(s)) \right) ds.
\]

Here again we refer the reader to [25] for a version of Itô’s formula on compact Riemannian manifolds. It provides in our case the same expression as in [12].

The collection \( \varphi^{\varphi,i}_A = (\varphi^{\varphi,i}_A)_{A \subset \mathbb{Z}^d} \) forms an interaction potential on \( \tilde{\Omega} \) depending on events that depend only on times between 0 and \( t \). Let \( H^\varphi \) denote the Hamiltonian associated with
\( \Phi^{\varphi, t} \); then we can write finally
\[
Q_{A, y}^{x_A}(dX_A) = \exp \left( -H_{A, y}^{\varphi}(X_A) \right) \bigotimes_{j \in A} \rho^{\circ \cdot x_j}(dX_j)
\]
and analogously for the decoupled measure
\[
Q_{A, i, y}^{x_A}(dX_A) = \exp \left( -H_{A, i, y}^{\varphi}(X_{A \setminus i}) \right) \bigotimes_{j \in A \setminus i} \rho^{\circ \cdot x_j}(dX_j) \otimes \rho^{\circ \cdot x_i}(dX_i).
\]

So far we have established a nice representation for \( Q_{A, y}^{x_A} \) with a new interaction \( \Phi^{\varphi, t} \). The terms in the expression \( \Phi^{\varphi, t} \) are of finite range and the derivatives of \( \varphi \) are bounded, so \( \Phi^{\varphi, t} \) is of finite range too. Let us repeat here that we wrote the measure \( Q_{A, y}^{x_A} \) (or \( Q_{A, i, y}^{x_A} \)) as a measure w.r.t. a product of independent Brownian motions on the circle, like for the unbounded spin case in [12].

All dependences are now shifted to the term \( \exp(-H_{A, y}^{\varphi}(X_A)) \) which we will control using a cluster expansion. Our next goal will be to show that those dependences are small if \( t \) is small. Due to its form it is clear that there exists a constant \( C > 0 \) such that for any \( X \) and \( A \subset \mathbb{Z}^d \)
\[
|\Phi^{\varphi, t}_A(X)| \leq C \left( t + \sup_{j \in A} |X_j(t) - X_j(0)| \right).
\]

Let us turn back to the Radon–Nikodým derivative given by Lemma 3.1. We will now perform a cluster expansion of the numerator:
\[
\mathbb{E}_{Q_{A}^{x_A}}(\exp(f_{A, y}(X_A)(t) - f_{A, y}(X_A))).
\]

The one for the decoupled measure works analogously. Thanks to (9) we can express the above expression (11) as
\[
\mathbb{E} \bigotimes_{j \in A} \rho^{\circ \cdot x_j} \left( \exp \left( - \sum_{A \subset A} \psi^{y, A, t}_A(X_A) \right) \right)
\]
where \( \psi^{y, A, t}_A \) is the interaction potential on \( C([0, 2\pi]^A) \) given by
\[
\psi^{y, A, t}_A(X_A) = \Phi^{\varphi, t}_A(X) - \varphi_A(X(t)) + \varphi_A(X(0)) + \sum_{B \cup A = A} (\varphi_B(X_A(t)_{Y_A^c}) - \varphi_B(X_A(0)_{Y_A^c})).
\]

Note that \( \psi^{y, A, t}_A \) satisfies the same bound as in (10). Furthermore we remark that Girsanov’s theorem gave us the representation of the expectation w.r.t. a product measure.

Now we want to turn to the space–time cluster expansion. It is basically as in [12], so we will just recall some essential steps. Let a collection of \( n \) sets be a cluster, \( \gamma = \{A_1, \ldots, A_n\} \), and let \( \mathcal{L}_A \) be the set of all clusters with disjoint supports. Then we can expand
\[
\mathbb{E} \bigotimes_{j \in A} \rho^{\circ \cdot x_j} \left( \exp \left( - \sum_{A \subset A} \psi^{y, A, t}_A(X_A) \right) \right)
\]
\[
= \mathbb{E} \bigotimes_{j \in A} \rho^{\circ \cdot x_j} \left( 1 + \sum_{n \geq 1} \sum_{\gamma_1, \ldots, \gamma_n} \prod_{i=1}^n \mathcal{K}^{y, A, t}(\gamma_i)(X) \right)
\]
where
The clusters in \( \mathcal{L}_A \) have disjoint supports; thus we can write the expectation of the product as a product of the expectations:

\[
1 + \sum_{n \geq 1} \sum_{\{y_1, \ldots, y_n\} \in \mathcal{L}_A} \prod_{i=1}^{n} \mathbb{E}_{\rho_{\otimes, x_j}} (K^{y, A, t}_x(y_i))(X_i).
\]

We will use the abbreviation \( K^{y, A, t}_x(y_i) := \mathbb{E}_{\rho_{\otimes, x_j}} (K^{y, A, t}_x(y_i))(X_i) \), which plays the role of a “weight” on the cluster. So finally we obtain the representation

\[
\mathbb{E}_{\rho_{\otimes, x_j}} \left( \exp \left( - \sum_{A \subset A} \psi^{y, A, t}_A(X_A) \right) \right) = 1 + \sum_{n \geq 1} \sum_{\{y_1, \ldots, y_n\} \in \mathcal{L}_A} \prod_{i=1}^{n} K^{y, A, t}_x(y_i).
\]

The following lemma gives us an estimate for the weights of the clusters. It is the same as in [12] and the only difference is the state space of the spins. We refer the reader to [12] for the proof and remark that the key ingredient is here the existence of all exponential moments for the Brownian motion on the circle.

**Lemma 3.2.** There exists a function \( \lambda(t) > 0 \) which tends to 0 as \( t \) goes to 0, such that for any \( y, x \in [0, 2\pi)^d \), \( A \subset \mathbb{Z}_d \) finite and connected clusters \( \gamma \in \mathcal{A} \) we have the following estimate:

\[
|K^{y, A, t}_x(\gamma)| \leq \lambda(t) 2^y.
\]

Now we intend to deduce from the previous lemma that for \( t \) small enough and incompatible clusters \( \gamma \in \mathcal{A} \)

\[
\sup_{x, y \in [0, 2\pi]^d} \sup_{A \subset \mathbb{Z}_d} \sum_{\gamma' \in \mathcal{A} \setminus \mathcal{A}} |K^{y, A, t}_x(\gamma')| \exp(\#\gamma') \leq 2\gamma.
\]

In the following we use the Kotecký–Preiss condition from [22]. In that paper the authors prove that if there are two positive functions \( a \) and \( d \) on the set of polymers such that one has for the polymer weights \( \Phi \) and incompatible clusters \( C \) the following inequality:

\[
\sum_{C, C' \text{ incomp.}} \exp(a(C') + d(C'))|\Phi(C')| \leq a(C)
\]

then the log of the partition function admits a unique cluster expansion. The criterion (13) is satisfied by (12) for \( d = 0 \) and \( a = | \cdot | \). Let us mention that the convergence criteria could be improved in [26].

Thus we can apply the cluster expansion following Kotecký and Preiss and get a unique expansion of the logarithm of the expectation:

\[
\ln \left( \mathbb{E}_{Q_{A}}^{\mathcal{A}} \left( \exp \left( -\tilde{H}_{A, A^c}^{\hat{\phi}}(X_A(t), y) + \tilde{H}_{A, A^c}^{\hat{\phi}}(x, y) \right) \right) \right) = \ln \left( 1 + \sum_{n \geq 1} \sum_{\{y_1, \ldots, y_n\} \in \mathcal{L}_A} \prod_{i=1}^{n} K^{y, A, t}_x(y_i) \right) = \sum_{n \geq 1} \sum_{\{y_1, \ldots, y_n\} \in \mathcal{M}_A} a(y_1, \ldots, y_n) K^{y, A, t}_x(y_1) \cdots K^{y, A, t}_x(y_n)
\]
with \( a(\gamma_1, \ldots, \gamma_n) \in \mathbb{R} \) coming from the Taylor expansion of the logarithm and where \( \mathcal{M}_A \) was the set of connected clusters whose supports are connected too. For the \( i \)-decoupled measure we have the same expression except that we sum over \( \mathcal{M}_{A\setminus i} \), the set of all clusters in \( A \setminus i \) whose support is connected too. Therefore the log of the ratio \( \frac{dv'_{A,y}}{dv'_{A,y}}(x_A) \) provides

\[
\sum_{n \geq 1} \sum_{\{\gamma_1, \ldots, \gamma_n\} \in \mathcal{M}_A} a(\gamma_1, \ldots, \gamma_n) K^{y,A,t}_x(\gamma_1) \ldots K^{y,A,t}_x(\gamma_n) - \sum_{n \geq 1} \sum_{\{\gamma_1, \ldots, \gamma_n\} \in \mathcal{M}_{A\setminus i}} a(\gamma_1, \ldots, \gamma_n) K^{y,A,t}_x(\gamma_1) \ldots K^{y,A,t}_x(\gamma_n) = \sum_{n \geq 1} \sum_{\{\gamma_1, \ldots, \gamma_n\} \in \mathcal{M}_{A\setminus i}} a(\gamma_1, \ldots, \gamma_n) K^{y,A,t}_x(\gamma_1) \ldots K^{y,A,t}_x(\gamma_n) \quad (14)
\]

for \( t \) small. The bound in (12) is uniform in \( x, y \) and \( A \); thus again using [22] we can conclude that the former series (14) converges uniformly in \( x, y \) and \( A \). Take an arbitrary connected cluster \( \gamma' \); then

\[
\mathbb{E} \otimes_{j \in A} \rho^0 \otimes_{x_j} \left( \prod_{A \in \gamma'} \left( \exp \left( -\Psi^{y,A,t}_A(X_A) \right) - 1 \right) \right) \rightarrow_{A \rightarrow \mathbb{Z}^d} \mathbb{E} \otimes_{j \in \mathbb{Z}^d} \rho^0 \otimes_{x_j} \left( \prod_{A \in \gamma'} \left( \exp \left( -\Psi^{y}_A(X) \right) - 1 \right) \right)
\]

and it follows using the Lebesgue dominated convergence theorem that \( \frac{dv'_{A,y}}{dv'_{A,y}}(x_A) \) converges uniformly in \( x, y \) towards \( \exp(-\tilde{H}^{y}_i(x)) \exp(G^{y}_i(x)) \) with

\[
G^{y}_i(x) = \sum_{n \geq 1} \sum_{\{\gamma_1, \ldots, \gamma_n\} \in \mathcal{M}_{i \setminus y}} a(\gamma_1, \ldots, \gamma_n) K^{y}_x(\gamma_1) \ldots K^{y}_x(\gamma_n).
\]

Because of the weak convergence of \( v'_{A,y} \) towards \( v' \), as well as for the decoupled measures, one has for each \( i \) that \( v'(dx) = \exp(-\tilde{H}^{y}_i(x) + G^{y}_i(x))v'^{i: i}(dx) \). For \( g \) a local bounded function from \([0, 2\pi]^A \) to \([0, 2\pi]\)

\[
\int_{[0, 2\pi]^2} g(x_A) v'(dx) = \lim_{A \rightarrow \mathbb{Z}^d} \int_{[0, 2\pi]^A} g(x_A) v'_A(dx_A)
\]

and thus it follows that the measures \( v'(dx) \) and \( \exp \left( -\tilde{H}^{y}_i(x) + G^{y}_i(x) \right) v'^{i: i}(dx) \) coincide for each \( i \) and that the RN derivative is continuous.

The product measure on \([0, 2\pi]^{A\setminus i} \times [0, 2\pi], v'^{i: i}_A \), is the measure of the decoupled dynamics with decoupled initial condition. This projection on the \( i \)-th coordinate is the Haar measure \( \frac{1}{2\pi} dx \). Therefore \( v'^{i: i} \) is a product measure on \([0, 2\pi]^{2^{A\setminus i}} \times [0, 2\pi] \) with also the Haar measure as the projection on the \( i \)-th coordinate.
Altogether we get for \( t \) small that \( \nu^t \) is a Gibbs measure associated with the Haar measure as reference measure with interaction \( \varphi^t \) given by

\[
\varphi^t_A(x) = \tilde{\varphi}_A(x) - \sum_{n \geq 1} \sum_{(\gamma_1, \ldots, \gamma_n) \in \mathcal{M}_A} a(\gamma_1, \ldots, \gamma_n) K^t_x(\gamma_1) \cdots K^t_x(\gamma_n).
\]

We conclude that for \( t \) small the time-evolved interaction is a small perturbation of the initial interaction. There exists a time-evolved interaction \( \varphi^t \) which is given by the above equation and depends on \( \tilde{\varphi} \) and \( \varphi \) and is absolutely summable, since \( \tilde{\varphi} \) and \( \varphi \) are absolutely summable. For the case where the initial measure \( \nu \) is an extremal Gibbs measure we have proven that \( \nu^t \) (associated with \( \varphi^t \)) is Gibbs too, i.e. \( \nu^t \in \mathcal{G}(\varphi^t, \frac{1}{2\pi} dx) \). It is even extremal in the set \( \mathcal{G}(\varphi^t, \frac{1}{2\pi} dx) \).

An arbitrary Gibbs measure is a mixture of extremal Gibbs measures so if we take any average over extremal Gibbs measures we get the result for a general \( \nu \).

3.2. High temperatures at arbitrary times

Now we look at arbitrary times \( t \). We consider the infinite-dimensional gradient system where both the initial and the dynamical interactions are small. We will introduce a drift term \( U \) to get a perturbation expansion around it. Let us recall the definition of the system

\[
\begin{cases}
dX_i(t) = -\frac{1}{2} U'(X_i(t)) dt - \frac{\beta}{2} \nabla_i H^\varphi_i(X(t)) dt + dB^\odot_i(t), & i \in \mathbb{Z}^d, \ t > 0 \\X(0) \simeq \nu, \ t = 0
\end{cases}
\]

and for \( \beta = 0 \)

\[
\begin{cases}
dX_i(t) = -\frac{1}{2} U'(X_i(t)) dt + dB^\odot_i(t), & i \in \mathbb{Z}^d, \ t > 0 \\X(0) \simeq \nu, \ t = 0.
\end{cases}
\]

We note that the only difference from the previous section is that here the single-site term \( U \) is not included in \( H^\varphi \) but considered separately. The initial interaction \( \tilde{\varphi} \) will always be a “high-temperature interaction”, so it satisfies condition (1). Therefore we will always start in a unique Gibbs measure \( \nu \). Furthermore we distinguish, like in the previous part, between the case where the dynamical interaction is an infinite-temperature one, like system (16), which means that the evolution follows independent Brownian motions with drift moving on circles, and the system defined in (15) including both high- and infinite-temperature dynamics. We assume that \( U \) is at least \( C^2([0, 2\pi]) \).

**Theorem 3.2.** Let \( U \) be a \( C^2 \)-function, let \( \tilde{\varphi} \) be a high- or infinite-temperature interaction and let the finite-dimensional dynamical interaction \( \varphi_A \) be \( C^2 \), for all \( A \). Let \( \beta \) be the inverse temperature. Furthermore let \( Q^\nu_\beta \) be the law of the solution of (15) on \( \tilde{\Omega} \) with the unique \( \nu \in \mathcal{G}(\tilde{\varphi}, m) \) and \( m \) given by \( m(dx) = \frac{1}{2\pi} e^{-U(x)} \frac{1}{2\pi} dx \). Then there exists an inverse temperature \( \beta_0 := \beta_0(\tilde{\varphi}, \varphi) > 0 \) such that for any \( \beta \leq \beta_0 \) and any \( t \) there exists an interaction \( \varphi^t \) which is absolutely summable, and which has as a Gibbs measure \( \nu^t_\beta = Q^\nu_\beta \circ X(t)^{-1} \in \mathcal{G}(\varphi^t, m) \).

**Proof.** Here again the proof follows essentially that of [12]. Note that in our case the ultracontractivity condition on \( U \) is automatically satisfied, and the same holds for the balance condition on \( U \) and the dynamical potential \( \varphi \), namely

\[
\sup_{A \subseteq \mathbb{Z}^d} \sup_{i \in A} \sup_{x \in [0, 2\pi]^4} |U'(x_i) \cdot \nabla_i \varphi_A(x)| < \infty.
\]
Ultracontractivity assures an exponentially fast convergence of the system to equilibrium, see Ref. [39]. Since now we want to look at arbitrarily large times and are not restricted to a perturbative result around the initial measure, we need to use different techniques, just like the authors of [12]. A sketch of the proof follows. We will leave out some of the steps and refer the reader to [12] for those, when they are the same.

In the first step we compute the density of $Q^{X,Λ}_{β,A}$ with respect to $Q^{X,Λ}_{0,A}$, so we compare the difference evolving with high- or infinite-temperature dynamics after some time, to show that the time-evolved measure is a small perturbation of the free ($β = 0$) one. Again using cluster expansion techniques, with $β$ as the small parameter, we are able to show that the Radon–Nikodým derivative of these measures will turn out to be small. So it does not make much difference if the system evolves with high- or infinite-temperature dynamics. Next we study the Gibbsian character of the joint distribution $Q^{v}_{β}$, so we compare the conditional probabilities $Q^{v}_{β} = Q^{v}_{β} ◦ (X(0), X(t))^{-1}$ on the space $C(S)$ instead of $v'$ directly. This measure will turn out to be Gibbs. It is associated with some interaction $H'$ which will depend on the initial Hamiltonian, the terms from the cluster expansion and a two-body potential induced by $p_t^{⊙,U}$ (the transition probability of a Brownian motion on the circle with drift $U'$ which depends only on the single sites $i$). The next lemma again closely parallels one from [12].

**Lemma 3.3.** The measure $Q^{v}_{β}$ is a Gibbs measure on the bi-space associated with the reference measure $m ⊗ m$ on $[0, 2π) × [0, 2π)$ and formal Hamiltonian function $H'$ given by

$$H'_Λ(x, y) = \tilde{H}'_Λ(x) - \sum_{i ∈ Δ} \log (p_i^{⊙,U}(x_i, y_i)) + \sum_{A ⊆ Z^d \setminus Δ \neq ∅} \Phi^{β,t}_A (x, y).$$

(17)

The main argument uses the fact that both $ψ$ and $Φ^{β,t}_A$ (which comes from the cluster expansion) are high-temperature interactions for sufficiently low $β$, so that the set of Gibbs measures on $([0, 2π) × [0, 2π)]^{Z^d}$ associated with $H'$ and reference measure $m ⊗ m$ contains at most one element. Taking the natural bijection between $([0, 2π) × [0, 2π)]^{Z^d}$ and $S$ we obtain the desired result.

By integrating out the first layer we are able to show the existence of a regular density $f_{A,β}^t$ for which the conditional probabilities

$$v'^t_β(dz_A|y_{A'}) = f_{A,β}^t(z_A y_{A'}) m^{⊗,A}(dz_A)$$

exist. Using Kozlov’s representation theorem [27] we will identify this measure to be Gibbs. More precisely let $Λ ⊆ Z^d$ be a finite box. We fix the boundary condition in the second layer $X_{A'}(t) = y_{A'}$ and note that this measure $Q^{v,y_{A'}}_{β} := Q^{v}_{β} (\cdot | X_{A'}(t) = y_{A'})$ is Gibbs on $[0, 2π)^{Z^d} × [0, 2π]$ for $y_{A'}$. Integrating out w.r.t. the first layer we get that for almost all $y_{A'}$, $v'^t_β (\cdot | y_{A'})$ is the marginal of $Q^{v,y_{A'}}_{β}$. It is easy to see that there exists a regular density $f_{A,β}^t$ such that

$$v'^t_β(dz_A|y_{A'}) = f_{A,β}^t(z_A y_{A'}) m^{⊗,A}(dz_A)$$

for $y ∈ [0, 2π)^{Z^d}$ given by

$$f_{A,β}^t(y) = \int_{[0, 2π)^{Z^d}} \frac{1}{Z_A(y_{A'})} \prod_{i ∈ A} p_i^{⊙,U}(x_i, z_i) \exp \left( \sum_{A ⊆ Z^d \setminus Δ \neq ∅} \Phi^{β}_A (x, z_A y_{A'}) \right) Q^v_{β}(dx).$$
for $Q^y_{\beta} (dx)$ a probability measure on $[0, 2\pi)^{2d}$. Finally we can analogously demonstrate the assumptions for Kozlov’s representation theorem; see [27]:

**Lemma 3.4.** For any $\Lambda$, $f^t_{\Lambda, \beta}$ satisfies the following properties:

1. $\exists C_1, C_2 > 0 : C_1 \leq \inf_{y \in [0, 2\pi)^{2d}} f^t_{\Lambda, \beta} (y) \leq \sup_{y \in [0, 2\pi)^{2d}} f^t_{\Lambda, \beta} (y) \leq C_2$ and

2. $\lim_{\Delta \to \mathbb{Z}^d} \sup_{y,u,y: \Delta = u - \Delta} |f^t_{\Lambda, \beta} (y) - f^t_{\Lambda, \beta} (u)| = 0$

and thus the family of conditional probabilities is built on an absolutely summable interaction and is therefore Gibbs.

**Remark.** The authors of [12] prove in one of their corollaries that the evolved measure is a unique Gibbs measure for the evolved interaction if either the time is large enough or for all times when the system evolves with an infinite-temperature dynamics. The argument goes essentially the same with less complication in our case; it uses the following argument. We already noticed that for $\beta$ small enough and $t$ large enough the potential on $S$ associated with $H^t$, as defined in (17), is a high-temperature interaction because it satisfies the high-temperature Dobrushin condition (1). A fortiori the specifications for this Hamiltonian are global, see [28], so the DLR equations also hold for unbounded subsets of the bi-space $S$. The uniqueness of the evolved measure follows then from this global property. □

### 4. Loss of the Gibbs property for the plane rotor in two dimensions

In this section we investigate what happens with the Gibbs measure for long times if one starts from the classical plane rotor model at a sufficiently low temperature in $\mathbb{Z}^2$ and evolves with independent Brownian motions moving on circles. We show that we can find a “bad configuration” for the time-evolved measure, which implies that after some time Gibbsianness gets lost.

In the spirit of [1, 13] we consider the joint distribution of the spins at time 0 and at time $t$, $Q^{\nu_\beta}$, which we already encountered in the previous section. Then we condition on a particular configuration at time $t$, $y^{\text{spec}}$, and show that this conditioning will create a set of alternating magnetic fields $(h_i(t))_{i \in \mathbb{Z}^2}$, so the configuration of a spin at site $i$ at time $t$ induces a local magnetic field $h_i(t)$. At time $t = 0$ these fields will provide two ground states and a phase transition (by breaking a discrete left–right symmetry) for the conditioned model for certain choices of configurations which make the model depend sensitively on variations of these configurations outside arbitrary large volumes. This “bad configuration”, $y^{\text{spec}}$, implies now non-Gibbsianness for the measure $\nu^t_\beta$. We see that the discontinuity w.r.t. the boundary at time $t$ when one conditions on the “bad value” comes from the existence of two distinct Gibbs measures for the conditioned system at time 0 (phase transition at time 0); compare Definition 2.1.

The process $X = (X_i(t))_{t \geq 0, i \in \mathbb{Z}^2}$ in this case is defined by the following system of SDE’s:

$$
\begin{cases}
\text{d}X_i(t) = \text{d}B^\varphi_{\beta}(t), & i \in \mathbb{Z}^2, \ t > 0 \\
X(0) \sim \nu_\beta, & t = 0
\end{cases}
$$

(18)

for $\nu_\beta \in \mathcal{G}_\beta (\varphi, \nu_0)$ and $\varphi$ of finite range and Lipschitz continuous and $\nu_0(dx) = \frac{1}{2\pi} \text{d}x$. We write the initial measure $\nu_\beta$ explicitly depending on the inverse temperature $\beta$, and we will consider the standard nearest neighbour interaction, which has a unique translation invariant pure Gibbs measure [29]. The main theorem that we want to prove is the following.

**Theorem 4.1.** Let $Q^{\nu_\beta}$ be the law of the solution $X$ of the planar rotor system (18) in $\mathbb{Z}^2$, $\nu_\beta \in \mathcal{G}_\beta (\varphi, \nu_0)$ and $\varphi$ given by $\varphi_{\beta,A}(x) = -\beta J \sum_{i,j \in A;i \sim j} \cos(x_i - x_j)$ for $x \in \Omega$, $J$ some
non-negative constant. Then there is a time interval \((t_0, t_1)\) such that for \(\beta\) large enough the measure \(\nu'_{\beta} = Q^{\psi_\beta} \circ X(t)^{-1}\) is not Gibbs, i.e. \(\nu'_{\beta} \notin \mathcal{G}_\beta(\psi', \nu_0)\) or in other words: one cannot find any version of its conditional probabilities which is a continuous function of the boundary condition (failure of quasilocality).

**Proof.** The outline of the proof is as follows. Like in the previous section we look at the joint law of the process at time 0 and time \(t\), \(Q^{\psi_\beta}\), on the bi-space \(S\). We fix a particular configuration at time \(t\), namely an alternating up–down configuration \(y^{\text{spec}}\), and show that the conditioned Hamiltonian \(H_{\beta}'(x, y^{\text{spec}})\) has two ground states for \(t\) large enough. By applying a percolation argument for low-energy clusters and discrete symmetry breaking from \([30]\), we will be able to prove that for sufficiently low temperatures \(|\mathcal{G}_\beta(H_{\beta}'(\cdot, y^{\text{spec}}), \nu_0)| \geq 2\), a phase transition occurs for the conditioned model at time 0. This means we have found a “bad configuration” \(y^{\text{spec}}\) for \(\nu'_{\beta}\) such that the measure will fail to be Gibbs.

We will rewrite the formal joint Hamiltonian originally given by

\[
H_{\beta}'(x, y) = \tilde{H}_\beta^\psi(x) + \sum_{i \in \mathbb{Z}^2} \log(p_i^\psi(x_i, y_i))
\tag{19}
\]

as

\[
H_{\beta}'(x, y) = \tilde{H}_\beta^\psi(x) + \sum_{i} \left(2e^{-t} \cos(x_i - y_i) + o(e^{-t})\right).
\tag{20}
\]

The kernel \(p_i^\psi(x_i, \cdot)\) in (19) was already defined in the previous section as the transition kernel of a Brownian motion on the circle starting from \(x_i\). It has the explicit form

\[
p_i^\psi(x_i, y_i) = \frac{1}{\sqrt{2\pi t}} \sum_{n \in \mathbb{Z}} \exp\left(-\frac{(y - x - 2n\pi)^2}{2t}\right)
\]

(see for example \([31]\)). Using the Poisson summation formula, see e.g. \([32]\), it equals

\[
p_i^\psi(x_i, y_i) = \frac{1}{2\pi} \left(1 + 2 \cdot \sum_{n=1}^\infty e^{-n^2 t} \cos(n(x_i - y_i))\right).
\]

We will use the latter for convenience. It allows us to neglect the above single-site correction terms \(o(e^{-t})\), in the Hamiltonian, which are bounded uniformly in \(x_i\) and \(y_i\) (by \(\text{Const} \times e^{-4t}\) in fact), and have the obvious symmetries, without changing the qualitative behaviour in the rest of the analysis. In the following we investigate the conditioned model. We choose an alternating up–down configuration at time \(t\), namely \(y^{\text{spec}} = (\mathbb{1}_{i \in 2\mathbb{N}+1} \pi, i \in \mathbb{Z}^2)\), which will yield two ground states. For convenience we call a spin \(x_i\) up if \(x_i = 0\) and down if it has the value \(\pi\). The spin \(x_i\) points to the right (resp. to the left) if \(x_i = \pi/2\) (resp. \(3/2\pi\)). By abuse of notation we say that \(i = (i_1, i_2) \in \mathbb{Z}^2\) is even if the sum of the components is even, i.e. \(i_1 + i_2 \in 2\mathbb{N}\), and odd otherwise. For example, the spin at the origin takes the value \(y^{\text{spec}}_{(0,0)} = y^{\text{spec}}_0 = 0\) and at position \((1,0)\) the value \(y^{\text{spec}}_{(1,0)} = \pi\) and so forth. Then we get the following ground states. \(\square\)

**Proposition 4.1.** Let \(\nu_\beta\) be a sufficiently low-temperature initial Gibbs measure with \(\beta = \beta(t)\) of order at most \(O(h(t))^{-2}\). Let the Hamiltonian of the conditioned joint system at time 0 and \(t\), \(H_{\beta}'(x, y)\), be defined in (20). Then we find the following two ground states for this Hamiltonian \(x^{\text{tr}} := (\pi/2 + (-1)^i \varepsilon_i, i \in \mathbb{Z}^2)\) and \(x^{\text{te}} := (3/2\pi + (-1)^i \varepsilon_i, i \in \mathbb{Z}^2)\) where \(\varepsilon_i > 0\) is of order \(O(h(t)/4\beta)\).
Proof. We plug $y^{\text{spec}}$ in (20) and obtain for the formal Hamiltonian
\[ H^f_{\beta}(x, y^{\text{spec}}) = \tilde{H}^f_{\beta}(x) + \sum_i \left( 2(-1)^i e^{-t} \cos(x_i) + o(e^{-t}) \right). \]

The initial formal Hamiltonian was chosen as
\[ \tilde{H}^f_{\beta}(x) = -\beta J \sum_{i \sim j} \cos(x_i - x_j) \]
where $J > 0$ is some nearest neighbour coupling term, which makes the initial system ferromagnetic. Now, we want to determine the configurations minimizing the Hamiltonian $H^f_{\beta}(x, y^{\text{spec}})$. We will here neglect the correction term. A configuration $x$ then is called a ground state if for each $i \in \mathbb{Z}^2$ the pair $(x_i, x_{i+1})$ is a minimal point of the real function
\[ \Phi^f_{\beta} : (z, y) \mapsto -\beta J \cos(z - y) + \frac{1}{4} h_i(t)(\cos(z) - \cos(y)) \]
with $h_i(t) := 2(-1)^i e^{-t} = (-1)^i h(t)$. We can safely forget about the correction term here, which is small with respect to the fields $h_i(t)$, and has the same (left–right) symmetry. Note that this interaction $\Phi^f_{\beta}$ is equivalent to the interaction of our Hamiltonian $H^f_{\beta}(x, y^{\text{spec}})$. In fact it is a sum of two competing terms. The term coming from the initial Hamiltonian wants neighbouring spins to point in the same direction and the other term, which comes from the conditioning at time $t$, tries to direct the spins in the specified up–down directions. They will find a compromise at pointing almost in the same direction with small corrections alternatingly “up” and “down” by the amount of $|\varepsilon_i|$. Let us assume that $i$ is even. We take derivatives of $\Phi^f_{\beta}(z, y)$ w.r.t. $z$ and $y$,
\[ \frac{\partial}{\partial z} \Phi^f_{\beta}(z, y) = \beta J \sin(z - y) - \frac{1}{4} h(t) \sin(z) \]
\[ \frac{\partial}{\partial y} \Phi^f_{\beta}(z, y) = -\beta J \sin(z - y) + \frac{1}{4} h(t) \sin(y). \]
Thus the point $(z, y)$ is stationary if
\[ \beta J \sin(z - y) = \frac{1}{4} h(t) \sin(z) \quad \text{and} \]
\[ \beta J \sin(z - y) = \frac{1}{4} h(t) \sin(y), \]
i.e. if $\sin(z) = \sin(y)$, which is the case if either $z = y$ or $z + y = \pi$. If $z = y$ then it follows from the conditions above that the only possible points are $(0, 0)$ and $(\pi, \pi)$. For the second case, if $z + y = \pi$, we need that
\[ \frac{4 \beta J}{h(t)} \sin(2z) = -\sin(z) \quad \text{and} \]
\[ \frac{4 \beta J}{h(t)} \sin(2y) = \sin(y) \]
which is equivalent to
\[ \sin(z) \left( 1 + \frac{8 \beta J}{h(t)} \cos(z) \right) = 0, \]
\[ \sin(y) \left( 1 - \frac{8 \beta J}{h(t)} \cos(y) \right) = 0. \]
So either \( \sin(z) \) and \( \sin(y) \) is equal to 0, which means that all the spins want to point in either
the 0 or the \( \pi \) direction ((0, 0) and (\( \pi, 0 \)), or \( \cos(z) = -\frac{h(t)}{8\beta J} \) and \( \cos(y) = \frac{h(t)}{8\beta J} \). For the
low-temperature regime, when \( \beta \) is very large, in fact we will choose \( \beta(t) = \beta \) at least of
order \( O(h(t)^{-2}) \), and since \( J > 0 \), the term \( \pm \frac{h(t)}{8\beta J} \) approaches 0 from above and from below,
respectively. Therefore \((z, y)\) has to be equal to \((\frac{\pi}{2} + \epsilon_t, \frac{\pi}{2} - \epsilon_t)\) or to \((3\frac{\pi}{2} + \epsilon_t, 3\frac{\pi}{2} - \epsilon_t)\),
respectively, for some \( \epsilon_t > 0 \) which depends on \( h(t) \). It will be of order at most \( O(h(t)/\beta J) \) (or \( O(h(t)^3) \) since we chose \( \beta \) at least \( O(h(t)^{-2}) \). Note that the assumption “\( i \) even” is reflected in
the sign of \( \epsilon_t \). For \( i \) odd the extremal points would be \((\frac{\pi}{2} - \epsilon_t, \frac{\pi}{2} + \epsilon_t)\) and \((3\frac{\pi}{2} - \epsilon_t, 3\frac{\pi}{2} + \epsilon_t)\),
respectively. Now we want to determine which configurations are the proper minima of \( \Phi^l_\beta \)
and therefore of \( H^l_\beta \). The second derivatives are

\[
\frac{\partial^2}{\partial z^2} \Phi^l_\beta(z, y) = \beta J \cos(z - y) - \frac{1}{4} h(t) \cos(z)
\]

\[
\frac{\partial^2}{\partial y^2} \Phi^l_\beta(z, y) = \beta J \cos(z - y) + \frac{1}{4} h(t) \cos(y)
\]

\[
\frac{\partial^2}{\partial z \partial y} \Phi^l_\beta(z, y) = -\beta J \cos(z - y) = \frac{\partial^2}{\partial y \partial z} \Phi^l_\beta(z, y).
\]

The determinant of the Hessian matrix is equal to \(-\frac{1}{16} h(t) \cos(z) \cos(y)\). It is strictly negative for
the points (0, 0) and (\( \pi, \pi \)) and strictly positive for \((\pm \frac{\pi}{2} - \epsilon_t, \pm \frac{\pi}{2} + \epsilon_t)\), and also for (0, \( \pi \) and
(\( \pi, 0 \), respectively. Therefore (0, 0) and (\( \pi, \pi \)) are saddle points. The latter two are maximal
points since \( \frac{\partial^2}{\partial z^2} \Phi^l_\beta(z, y)|_{(0, \pi)} = -\beta J - \frac{1}{4} h(t) < 0 \) for large times (\( \beta \) large enough). The same
is true for the point (\( \pi, 0 \)). Since

\[
\beta J \cos(2\epsilon_t) > \frac{1}{4} h(t) \sin(\epsilon_t) + \sigma(\epsilon^{-t}),
\]

which is true for \( t \) large, it follows that

\[
\frac{\partial^2}{\partial z^2} \Phi^l_\beta(z, y)|_{(\pi/2 + \epsilon_t, \pi/2 - \epsilon_t)} > 0
\]

and the same holds for the point \((3/2\pi + \epsilon_t, 3/2\pi - \epsilon_t)\). So these points are the only minima.
For an illustration we show what the ground states look like.

Now we are in a position to prove a phase transition at time 0. We will essentially follow
the arguments of [30]. By conditioning with the configuration \( y^{\text{spec}} \) at time \( t \) we have created
a discrete left–right symmetry for the continuous model at time 0. Now we want to prove via
percolation methods that there is a time interval \((t_0, t_1)\) for which a spontaneous symmetry breaking occurs. We will look at Gibbs measures which are obtained by taking infinite-volume limits of finite-volume Gibbs measures with periodic boundary conditions. The picture of what happens is the following: if the interaction exhibits a ground state degeneracy then the “low-energy ocean” is bound to show a pattern corresponding to one of the two distinct ground states. This pattern can be seen at infinity and the two possible values are symmetry related. A fortiori there exist two disjoint symmetry-related tail events with positive probability, which can only occur if the relating symmetry is broken.

One question that Georgii answers in [30] is that of under which conditions there exists a unique “low-energy” infinite cluster and when it implies that the system has a phase transition. Two adjacent sites have a low-energy interaction if for a given \(\delta > 0\), their energy is smaller than the ground state energy plus the correction term \(\delta\). The existence of a low-energy bond percolation will be implied by a low-energy site percolation on the dual lattice for our nearest neighbour potential having exactly two ground states.

We want to apply the general theorem of [30] to our special case. In the following we will check its assumptions for our interaction \(\Phi^t_\beta\) and give the main steps of the argument from [30]. We rewrite them to be able to apply it to our case. Georgii proves in [30] that low-energy clusters percolate at low temperatures for a general \(C\)-potential for general spins in \(d\) dimensions having \(N\) distinct ground states. Our case is two-dimensional; we have compact spins and a potential which is a simple nearest neighbour potential having exactly two ground states.

Let \((\mathbb{Z}^2)^+\) indicate the dual lattice of the square lattice, i.e. \((\mathbb{Z}^2)^+ = \mathbb{Z}^2 + (1/2, 1/2)\). Each point \(a\) in \((\mathbb{Z}^2)^+\) is identified with the elementary cube consisting of four sites of \(\mathbb{Z}^2\), i.e.

\[
a \equiv \{ i \in \mathbb{Z}^2 : i = a + (\pm 1/2, \pm 1/2) \}.
\]

Let \(v = \{ (0, 0), (0, 1), (1, 1), (1, 0) \} \equiv (1/2, 1/2)\) be the elementary cube at the origin of \((\mathbb{Z}^2)^+\). We will write the formal Hamiltonian \(H^t_\beta\) as a Hamiltonian on the dual lattice, i.e. of the form \(H^t_\beta(x) = \sum_{a \in (\mathbb{Z}^2)^+} \Phi^t_\beta(a, x)\), where \(\Phi^t_\beta : (\mathbb{Z}^2)^+ \times \Omega \to \mathbb{R}\) is such that:

1. There is a function \(\Phi^t_{v, \beta} : [0, 2\pi)^4 \to \mathbb{R}\) with \(\Phi^t_\beta(v, x) = \Phi^t_{v, \beta}(x)\) for all \(x\). This is trivially satisfied since we can set \(\Phi^t_{v, \beta}(x) = \frac{1}{2} \sum_{i, j \in v} \Phi^t_\beta(x_i, x_j)\). Our symmetric interaction \(\Phi^t_\beta(x_i)\) can be written as a sum over adjacent sites \(\Phi^t_\beta(x_i, x_j)\).
2. Translation and reflection invariance w.r.t. the horizontal and vertical plane at 1/2 are also trivially satisfied, since our nearest neighbour potential is symmetric.
3. \(\Phi^t_{v, \beta}\) is also continuous and we set \(m \equiv \inf \Phi^t_{v, \beta}\).

We introduce in the sense of Georgii a low-energy site percolation on the dual lattice as follows. Let \(\delta > 0\) be fixed; then for each configuration \(x \in \Omega\) a subgraph \(G_\delta(x) = (V_\delta(x), E_\delta(x))\) of \((\mathbb{Z}^2)^+\) consists of the vertex set

\[
V_\delta(x) = \{ a \in (\mathbb{Z}^2)^+ : \Phi^t_{v, \beta}(a, x) \leq m + \delta \}
\]

and edges connecting adjacent sites in \(V_\delta(x)\). Let \(C_\delta\) denote the cluster built on sites of \(G_\delta(x)\). \(\{ |C_\delta| = \infty \}\) denotes the event that there is an infinite cluster \(C_\delta\) built on low-energy configurations. The graph \(G_\delta\) describes the corresponding low-energy clusters on the dual lattice. Now we can prove the following.

**Proposition 4.2.** For \(\beta(t)\) large enough there is a time interval \((t_0, t_1)\) such that \(|\mathcal{G}_\beta(H^t_\beta(\cdot, y^{\text{spec}}), v_0)| \geq 2\).
Proof. The proof of this proposition will consist of proving two lemmas. First we prove the existence of a unique low-energy cluster and afterwards we deduce from that the spontaneous breakdown of discrete symmetry and the existence of at least two distinct infinite-volume Gibbs measures. We will basically apply the proofs of Georgii’s paper, [30], to our simpler case. We consider finite-volume Gibbs distributions $v_{\beta, A}^t$, corresponding to the joint system conditioned at time $t$ with periodic boundary conditions, that is

$$v_{\beta, A}^t(dx) = \frac{e^{-H(x, y_{\text{spec}})}}{Z_{y_{\text{spec}}}} v_0 \otimes A(dx),$$  

(21)

with $A = A_n$.

The next lemma is a time-dependent version of Theorem 3.7 from [30]. In our version the inverse temperature has an additional dependence on time. But the proof of the lemma follows essentially the proof of Theorem 3.7 from [30].

Lemma 4.1. Let $(\mathbb{Z}^2)^*$ indicate the dual lattice of the square lattice. Let $\delta > 0$ and $a \in (\mathbb{Z}^2)^*$ be fixed. Then for sufficiently large $\beta(t)$ there is a time interval $(t_0, t_1)$ such that there exists a.s. a unique infinite cluster $C_\delta$ for at least one translation invariant Gibbs measure $v_{\beta, t}^t$, i.e.

$$v_{\beta, t}^t(\exists! |C_\delta| = \infty) > 0.$$  

(22)

We will sketch the proof of this lemma. The main ingredient which does the work is the following estimate (which is the time-dependent version of Georgii’s Lemma 4.1).

Lemma 4.2. Let for each $a \in A^* \subset (\mathbb{Z}^2)^*$ the function $f_a, f_a : [0, 2\pi)^v \rightarrow [0, \infty)$, be given. $f_a$ is invariant under reflections of $v$. Then for all $\beta$

$$\int \prod_{a \in A^*} f_a(x_a) v_{\beta, A}^t(dx) \leq \prod_{a \in A^*} \left[ \prod_{b \in A^*} f_a(x_b) v_{\beta, A}^t(dx) \right]^{1/|A|}.$$  

(23)

This estimate is a consequence of the chessboard estimates which follow from the reflection positivity of $v_{\beta, A}^t$ w.r.t. reflections in the pairs of hyperplanes $R_1$ and $R_2$, where

$$R_k = \{z \in \mathbb{R}^2 : z_k = 0 \text{ or } n\}.$$  

To see the reflection positivity, Georgii points out that given the spin configuration in $A \cap R_k$, the spins in the remaining two parts are conditionally independent and up to reflections identically distributed. This applies clearly to our measure $v_{\beta, A}^t$. Using this inequality as a main ingredient, Georgii manages to show that for a fixed $\delta > 0$ the probability that there exists an infinite low-energy cluster $C_\delta$ in the dual lattice including the origin tends to 1 as $\beta$ is going to infinity. His argument on the uniqueness of the low-energy cluster is based on translation invariance of $v_{\beta, t}^t$, which is also trivially satisfied in our case. □

Reflection positivity of the measure and the estimate given above provide now the following lemma corresponding to Lemma 4.2 from [30].

Lemma 4.3. There is a function $r : [0, \infty) \rightarrow [0, 1]$ with $r(\beta) \rightarrow 0$ for $\beta \rightarrow \infty$ such that for all positive $\beta$ and $v_{\beta}^t \in \mathcal{G}_{0, \beta}(\Phi_{v, \beta}, v_0)$ and all finite $D \subset (\mathbb{Z}^2)^*$ the inequality

$$v_{\beta}^t(V_\delta(\cdot) \cap D = \emptyset) \leq r(\beta)^{|D|}$$

holds.
The lemma states that the probability that in any finite set $D$ of the dual lattice there are no points coming from the low-energy cluster vertices $V_\delta$ is going to 0 for large $\beta$. From this lemma he can conclude the existence of an infinite cluster. In fact the function $r$ is given by $r(\beta) = 1 + c e^{-\beta \delta}$ for some constant $c_\delta$ depending on $\delta$. Uniqueness can be deduced now from FKG inequalities and the 0–1 law for tail events or Georgii’s argument which is heavily based on translation invariance of the measure.

In the following we want to prove that the existence of a unique infinite low-energy cluster implies the existence of Gibbs measures in $G_{\mu}(\Phi^{t}, \nu_0)$ for which the discrete left–right symmetry is broken. We will prove the following statement which we borrow from [30] in our simpler case.

**Lemma 4.4.** Suppose there is an $\delta > 0$ such that the set $\{x \in [0, 2\pi]^v : \Phi_0(x) \leq m + \delta\}$ splits into two disjoint sets $A^{ri}$ and $A^{le}$ satisfying the stability and symmetry condition. Let $\beta$ be large such that $\nu_0^v(\exists!|\mathcal{C} \mid = \infty) > 0$ for some $\nu_0^v \in G_{\mu}(\Phi^{t}, \nu_0)$. Then there are at least two distinct measures: extremal Gibbs measures $\nu_0^{v^{ri}}$ and $\nu_0^{v^{le}}$.

**Proof.** We basically adapt the proof given in [30] for our case, where we have a left–right symmetry which we want to break, and two symmetry-related ground states.

Let $\delta > 0$ and let us look at the set $\{x \in [0, 2\pi]^v : \Phi_0(x) \leq m + \delta\} \subset [0, 2\pi]^v$. This is the set of all configurations which correspond to a rise of energy by the amount of $\delta$ away from the ground state. Clearly this set splits into two disjoint measurable sets $A^{ri}$ and $A^{le}$, since we have exactly two ground states $x^{ri}$ and $x^{le}$. This splitting is also stable in the sense of Georgii, because two elements can only coincide on an edge of $v$ if they come from one of the sets $A^{ri}$ or $A^{le}$ (spins in $A^{ri}$ point to the right and those in $A^{le}$ point to the left).

Let $r_i : [0, 2\pi]^v \to [0, 2\pi]^v$, for $i = 1$ or 2, be the reflections of $v$ with respect to the hyperplanes $\{z = (z_1, z_2) : z_i = 1/2\}$. Let $x$ be a configuration on $[0, 2\pi]^d$ and let $A \subset [0, 2\pi]^v$. Georgii constructs a graph $G_A(x) = (V_A(x), E_A(x))$ in the following way. The vertices $V_A(x)$ are those sites for which

$$x_a \in \begin{cases} A & \text{if } a \equiv v \mod 2 \\ r_1(A) & \text{if } a \equiv v + (1, 0) \mod 2 \\ r_2(A) & \text{if } a \equiv v + (0, 1) \mod 2 \\ r_1(r_2(A)) & \text{if } a \equiv v + (1, 1) \mod 2. \end{cases}$$

(24)

The set $r_1(A)$ (resp. $r_2(A)$) is the set $A$ reflected through the vertical (resp. horizontal) line at $1/2$. Similarly, $r_1(r_2(A))$ denotes the set $A$ after being reflected first horizontally and then vertically. For a graph built on $A^{ri}$, this means that we collect $a$ for which

$$x_a \in \begin{cases} A^{ri} & \text{if } a \equiv v \mod 2 \text{ or } a \equiv v + (0, 1) \mod 2 \\ A^{le} & \text{if } a \equiv v + (1, 0) \mod 2 \text{ or } a \equiv v + (1, 1) \mod 2. \end{cases}$$

(25)

and for $A^{le}$ the graph is the same up to an $r_1$-reflection.

This implies that each cluster $C_\delta$ of the graph $G_\delta(x)$ is a cluster $C_A^{ri}$ of $G_A^{ri}(x)$ or $G_A^{le}(x)$. Therefore the event that there exists a unique infinite cluster splits into a disjoint union of events that this infinite cluster appears in either $A^{ri}$ or $A^{le}$, namely

$$\{\exists!|C_\delta| = \infty\} = \{\exists!|C_A^{ri}| = \infty\} \cup \{\exists!|C_A^{le}| = \infty\}$$

where $\cup$ denotes the disjoint union. The splitting is also symmetric because of the simple relation $r_1(A^{le}) = A^{ri}$ (we have defined $r_1$ as the reflection w.r.t. the horizontal line at $z_1 = 1/2$). Thus
it follows that for $\nu^t_\beta \in G_{0,\beta}(\Phi^t_{v,\beta}, \nu_0)$
\[
\nu^t_\beta(\{\exists!|C_\delta | = \infty\}) = \nu^t_\beta(\{\exists!|C_{\delta'} | = \infty\}) \tag{26}
\]
and in particular that
\[
\nu^t_\beta(\{\exists!|C_\delta | = \infty\}) = 2\nu^t_\beta(\{\exists!|C_{\delta'} | = \infty\}).
\]
Since we know from the previous lemma that for $\beta$ large enough $\nu^t_\beta(\{\exists!|C_\delta | = \infty\}) > 0$ we have a fortiori
\[
\nu^t_\beta(\{\exists!|C_\delta | = \infty\}) > 0 \tag{27}
\]
which allows us to build conditional probabilities
\[
\nu^t_{\beta_{ri}} := \nu^t_\beta(\cdot|\{\exists!|C_{\delta'} | = \infty\})
\]
and
\[
\nu^t_{\beta_{le}} := \nu^t_\beta(\cdot|\{\exists!|C_{\delta} | = \infty\})
\]
which are orthogonal since $\{\exists!|C_{\delta'} | = \infty\}$ and $\{\exists!|C_{\delta} | = \infty\}$ are disjoint. The Gibbsianness of $\nu^t_{\beta_{ri}}$ and $\nu^t_{\beta_{le}}$ follows from the fact that $\{\exists!|C_{\delta'} | = \infty\}$ (resp. $\{\exists!|C_{\delta} | = \infty\}$) belongs to the tail $\sigma$-field $\mathcal{F}_\infty$. This is because the sets $\{\exists!|C_{\delta'} | = \infty\}$ (resp. $\{\exists!|C_{\delta} | = \infty\}$) are invariant under translations $\theta_i$, $i \equiv 0 \mod 2$, where $\theta_i$ denotes the translation by $i$. We have proved that the discrete symmetry $r_1$ is broken since there are at least two distinct Gibbs measures $\nu^t_{\beta_{ri}}$ and $\nu^t_{\beta_{le}}$. Finally we can conclude that, as mentioned before, the existence of distinct Gibbs measures for the conditioned double-layer system implies a point of essential discontinuity of the time-evolved measure which means that it is not a Gibbs measure. \qed

**Remark.** The above transition is one of the so-called spin-flop type.

### 5. Comments and possible generalizations

In this section we would like to discuss what kinds of generalizations of our results could hold. In our first class of results, the conservation of Gibbsianness, the restriction to finite-range potentials could be weakened, and also one could obtain results for $N$-component spins for general $N \geq 3$. For some developments in this direction, using Dobrushin uniqueness techniques, see [16].

A more sensitive question concerns the loss of the Gibbsian property. Although we have given the proof for the loss of Gibbsianness for the standard interaction in two dimensions, where the initial Gibbs state is presumably unique at all temperatures, the same arguments apply for other models, such as the nearest neighbour polynomial nonlinear models in two dimensions considered in [33].

An extension to the three-dimensional lattice is also immediate. In fact, because there is long-range order for any strength of the alternating magnetic field including zero, the non-Gibbsianness holds for all times larger than a certain $t_0$ in that case. Also the statement is true for any initial translation invariant (pure or not) Gibbs measure, of which there are known to be infinitely many [34,35].

Increasing the spin dimension and considering $N$-component spins is less immediate. For $d = 2$, our proof breaks down. For $d = 3$ however, a ferromagnet in a small alternating field displays continuous symmetry breaking in the plane perpendicular to the field [36]. A slight modification of our argument then again leads to non-Gibbsian behaviour.

A more serious limitation in our proof is that we used reflection positivity in our proof of the phase transition. This restricts the initial interactions quite severely (it should be a $C$-potential,
which is a generalized nearest neighbor potential), or a pair interaction of very specific form, and the dynamics needs to be an infinite-temperature one. To get rid of this limitation, one might hope to apply a Pirogov–Sinai type of approach. Dobrushin and Zahradník [37, 38] have obtained Pirogov–Sinai results for continuous spins. However, their conditions (quadratic interactions with general single-site potentials having Gaussian minima) do not directly apply. One might hope that their ideas could be modified to include our set-up; however, until now this has not been done. This seems a technically non-trivial question for future research.

Acknowledgements

We thank Christof Kulske and Alex Opoku for many discussions and for making the results of [16] available to us. Also we thank Roberto Fernández for a helpful discussion.
