In Archaea, bacteria, and eukarya, ATP provides metabolic energy for energy-dependent processes. It is synthesized by enzymes known as A-type or F-type ATP synthase, which are the smallest rotary engines in nature (Yoshida, M., Muneyuki, E., and Ishibashi, T., 2001) Nat. Rev. Mol. Cell. Biol. 2, 669–677; Imamura, H., Nakano, M., Noji, H., Muneyuki, E., Ohkuma, S., Yoshida, M., and Yokoyama, K. (2003) Proc. Natl. Acad. Sci. U. S. A. 100, 2312–2315). Here, we report the first projected structure of an intact A1A0 ATP synthase from Methanococcus jannaschii as determined by electron microscopy and single particle analysis at a resolution of 1.8 nm. The enzyme with an overall length of 25.9 nm is organized in an A1 headpiece (9.4 × 11.5 nm) and a membrane domain, A0 (6.4 × 10.6 nm), which are linked by a central stalk with a length of ~8 nm. A part of the central stalk is surrounded by a horizontal-situated rod-like structure (“collar”), which interacts with a peripheral stalk extending from the A0 domain up to the top of the A1 portion, and a second structure connecting the collar structure with A1. Superposition of the three-dimensional reconstruction and the solution structure of the A1 complex from Methanosarcina mazei Gø1 have allowed the projections to be interpreted as the A1 headpiece, a central and the peripheral stalk, and the integral A0 domain. Finally, the structural organization of the A1A0 complex is discussed in terms of the structural relationship to the related motors, F1F0 ATP synthase and V1V0 ATPases.

ATP synthases/ATPases are present in every life form and are the most important enzymes for the energy metabolism of the cell (1). They catalyze the formation of ATP at the expense of the transmembrane electrochemical ion gradient. They arose from a common ancestor that underwent structural and functional changes leading to three distinct classes of A1A0 complexes (F1F0,F1F0ATP synthase; V1V0 ATPase, vacuolar-type ATPase).

and V1V0 ATP synthases/ATPases. The V-type ATPases, found in organelles of eukaryotes, lost their ability to synthesize ATP. Their function is to create steep ion gradients at the expense of ATP hydrolysis (2). Archaea contain ATPases, the A1A0 ATP synthases, that are structurally similar to V1V0 ATPases but synthesize ATP like the F-type ATPases. The genomic sequences available today show that the overall subunit composition of the A1A0 ATP synthase is very similar to the V1V0 ATPases. For example, the A1A0 ATP synthases contain duplicated and even triplicated K subunits (proteolipids) (3, 4). The A1A0 ATP synthase has at least nine subunits (A3B3CDEFGHIK), but the actual subunit stoichiometry, especially regarding the proteolipid subunits K in A-type ATPases, is different in various organisms (12, 6, 4, or as suggested by genomic data, only 1 (5)). The A1A0 ATP synthase is composed of a water-soluble A1 ATPase and an integral membrane subcomplex, A0, ATP is synthesized or hydrolyzed on the A1 headpiece consisting of an A3B3 domain, and the energy that is provided for or released during that process is transmitted to the membrane-bound A0 domain (4). The energy coupling between the two active domains occurs via the so-called stalk part, an assembly proposed to be composed of the subunits C, D, and F (6, 7).

Insight in the molecular structure of the A-type ATP synthases comes from small-angle x-ray scattering data of the A1 ATPase from Methanosarcina mazei Gø1 whose A1 domain is made up of the five different subunits, A3B3CDF (8). The data have shown that the hydrated A1 ATPase is rather elongated with a headpiece of 10 × 9.4 nm in dimension and a stalk of ~8.4 nm in length. A comparison of the central stalk of this A1 complex with bacterial F1 and eukaryotic V1 ATPase indicates different lengths of the stalk domain (8, 9). Image processing of electron micrographs of negatively stained A1 ATPase from M. mazei Gø1 (7) has revealed that the headpiece consists of a pseudohexagonal arrangement of six masses surrounding a seventh mass. These barrel-shaped masses of ~3.2 and 2.8 nm in diameter and 7.5 and 5.0 nm in length, which consist of the major subunits A and B, are arranged in an alternating manner (7). The hexagonal barrel of subunits A and B encloses a cavity of ~2.3 nm in the middle in which part of the central stalk is asymmetrically located. The stalk protrudes from the bottom side of the headpiece forming an angle of ~20° with the vertical axis of the molecule. At the upper end of the hexagonal barrel, extensions can be observed that are assumed to belong to the N termini of subunit A (7). Further insights into the topology of the A1 ATPase were obtained by differential protease sensitivity (8) and cross-linking studies (6, 7). These studies
resulted in a model in which the subunits C, D (partly), and F form the central stalk domain (7).

However, in contrast to the related F- and V-type ATP synthases/ATPases, little is known regarding the overall structure of the A1A0 molecule, which is largely due to the instability of the isolated complexes (10). Most recently, an isolation procedure of the A1A0 ATP synthase of the hyperthermophilic Archaea Methanococcus jannaschii resulted in a complete and functionally coupled enzyme (11). Besides the property of being an enzyme of a hyperthermophilic organism whose multienzyme complexes are believed to be more stable than those of mesophiles, the M. jannaschii A1A0 ATP synthase is of particular interest because it has a K subunit three times the size of that of most bacteria and Archaea. Furthermore, this subunit has lost one of the ion translocating residues (12). Here, we used electron microscopy to visualize directly the structure of the A1A0 ATP synthase from M. jannaschii. A comparison with the low resolution structure of the A1 ATPase from M. mazei (77, 45, 25, 23, 11, 10, 77, and 21 kDa, respectively. A typical uranyl acetate. Images of the negatively stained A1A0 ATP synthase were collected on a Philips CM20FEG electron microscope operating at 200 kV and liquid N2-cooled specimen to reduce radiation damage. Images of 2,048 × 2,048 pixels (after a binning of 2) were recorded at ×67,200 magnification at a pixel size of 30 μm with a Gatan 4000 SP 4K slow-scan CCD camera with GRACE software for semi-automated specimen selection and data acquisition (16). Single particle analysis was performed with the GRIP (Groningen image processing) software package on a PC cluster. A total of 17,238 single particle projections (128 × 128 pixel frame; pixel size of 0.34 nm) from 331 images were obtained by selecting all of the discernable particles. For each micrograph, the defocus value was determined and a simple contrast transfer function correction by phase reversal was done (17). After band-pass filtering, the images were subsequently subjected to multireference alignment, multivariate statistical analysis, and hierarchical ascendant classification. This dataset was divided into two subsets including either one or two peripheral stalks to obtain a more homogenous dataset for a refinement of these classes. The subsets were analyzed in parallel by reference-free alignment (18). Each rotational and translational alignment was repeated four times, and classification was done by multivariate statistical analysis. Datasets were again divided and aligned as described above. The final classification of the homogenous datasets was performed by multivariate statistical analysis and hierarchical classification to extract the key structural features of the enzyme (19). The resolution of the class averages was measured according to van Heel (20).

RESULTS

Subunit Composition and Electron Microscopy—A characteristic gel of the preparation of the A1A0 ATP synthase from M. jannaschii is presented in Fig. 1A showing the nine subunits, A–F, H, I, and K, with apparent molecular masses of 66, 51, 45, 25, 23, 11, 10, 77, and 21 kDa, respectively. A typical electron microscopy raw image of the enzyme yields monodisperse particles with almost no contamination by smaller particles that could represent dissociated complexes or fragments (Fig. 1B). A total of 17,238 such molecular images were subjected to image processing. Fig. 2 demonstrates different class sums of the A1A0 ATP synthase projections obtained after several steps of reference-free translational/rotational alignment, multivariate statistical analysis, and multireference alignment. All of the projections reveal a tripartite structure consisting of a headpiece, a membrane-embedded domain, and a connecting stalk region. The classes can be grouped in respect

Structure and Subunit Topology of the $\alpha_1\beta_0$ ATP Synthase

**Fig. 2.** A gallery of selected classes resulting from the last multivariate statistical analysis and classification of 17,238 particles of the $\alpha_1\beta_0$ ATP synthase. Four classes (1–4) showing either one (A) or two (B) peripheral stalks besides the central stalk are shown.

**Fig. 3.** Total averages calculated from 410 (A), 497 (B), and 316 (C) images. C, a projection at around 40° compared with that in B. Bar represents 20 nm. Labels: black arrows, masses of the peripheral stalks connected with the $\alpha_1$ headpiece; white arrowhead, asymmetric upper part of the central stalk; black asterisk, mass connecting the $\alpha_0$ with the collar-like domain; white arrows, mass extending from the collar and the $\alpha_0$ domain.

The $\alpha_1\beta_0$ ATP synthase has been described as a chimeric enzyme combining the structural and functional features of F$_1$F$_0$ ATP synthases and V$_1$V$_0$ ATPases (4). Single particle analysis resulted in the visualization of projections of the $\alpha_1\beta_0$ ATP synthase from *M. jannaschii* consisting of an $\alpha_1$ headpiece and an $\alpha_0$ domain linked by a central stalk and two peripheral stalks. The $\alpha_1$ headpiece fits well with the projection of the recently determined three-dimensional reconstruction with the $\alpha_1$ complex from *M. mazei* Go1 composed of the hexagonal $\alpha_3\beta_3$ domain surrounding a cavity in which the central stalk subunit D is located (7, 8). The subunit is displaced toward an A-B-A triplet (7), allowing the rearrangements of the central D sub-

to the number of visible stalks: one group showing one peripheral stalk besides the central stalk (Fig. 2, frames A1–4; 12,555 particles) and a second group with two peripheral stalks on both the left and right side (Fig. 2, frames B1–4; 4,683 particles). To obtain more homogeneous classes, both data sets, including either two or three stalks, were analyzed separately as described under “Experimental Procedures.” Fig. 3 shows averages of each refined data set at a resolution of 1.8 nm (Fig. 3, A–C). In all of the averages, the $\alpha_1\beta_0$ ATP synthase from *M. jannaschii* has a total length of 25.9 nm. The dimensions of the $\alpha_1$ headpiece, the central stalk domain, and the membrane portion, $\alpha_0$, are $9.4 \times 11.5$, $8.0 \times 3.9$, and $6.4 \times 10.6$ nm, respectively. The $\alpha_0$ headpiece has a rather spherical mass that is clearly separated from the stalk domain at its base (Fig. 3B). The stalk domain is formed by a central stalk and either one (Fig. 3A) or two peripheral stalks (Fig. 3B). This observation might be explained either by some of the complexes being disrupted or by these classes containing complexes in different orientation. The central stalk can be divided into an asymmetric upper part and a collar-like structure located above the $\alpha_0$ domain. In the collar, several distinct densities could be resolved. At both ends of this domain, two such densities are connected to the peripheral stalks (Fig. 3B), which go all the way up to the $\alpha_1$ headpiece. One of these stalks appears to be in close contact with two areas of the $\alpha_1$ headpiece with one located at the outside and the second located on top of the $\alpha_3\beta_3$ headpiece (Fig. 3, B and C). This peripheral stalk shows a clear connection to the $\alpha_0$ portion via the collar structure (Fig. 3, B and C). By comparison, the second peripheral stalk is attached to the top of the $\alpha_1$ headpiece (Fig. 3C) and extended slightly down from the collar domain (Fig. 3B). A corresponding weak density rises up from the $\alpha_0$ (Fig. 3B). Whereas the peripheral stalk(s) seems to be connected to the outside of the $\alpha_0$ domain, the central stalk is attached to the center of the membrane-embedded $\alpha_0$, which appears as a rather symmetric flattened sphere and slightly tilted in most of the projections, especially in Fig. 2, frame B3.

**Localization of the Subunits Inside the $\alpha_1\beta_0$ ATP Synthase**—A known three-dimensional reconstruction of the asymmetrical $\alpha_1$ complex from *M. mazei* Go1 (7) determined from tilt pairs of negatively stained molecules was superimposed on the projection of the $\alpha_1\beta_0$ ATP synthase from *M. jannaschii* (Fig. 4, panel C) by rotating the $\alpha_1$ subcomplex in 5° steps through 360°. One of the projections of the $\alpha_1$ from *M. mazei* Go1 is well accommodated within the $\alpha_1$ headpiece, composed of the $\alpha_3\beta_3\gamma$ subassembly (7) and the upper central stalk, which is only partially (35%) solved in the three-dimensional reconstruction of the $\alpha_1$ ATPase from *M. mazei* Go1 (7). In this projection, one of the catalytic A subunits is on the right of the $\alpha_1$ domain, implying that the peripheral stalk on the right may be close to this major A subunit. Nevertheless, from the superposition of the $\alpha_1$ profile with the $\alpha_1$ part in the $\alpha_1\beta_0$ ATP synthase images, it is clear that the cap at the top of the $\alpha_1$ headpiece (Figs. 3B and 4C) does not belong to the $\alpha_3\beta_3\gamma$ subassembly. To further examine the composition of the central stalk, the projection of the $\alpha_1\beta_0$ ATP synthase from *M. jannaschii* was compared with the solution structure of the $\alpha_3\beta_3\gamma$ complex of the $\alpha_1$ ATPase from *M. mazei* Go1 deduced from solution x-ray scattering data (8). The central stalk of the hydrated $\alpha_3\beta_3\gamma$ complex, which consists of the subunits C, F, and a part of subunit D, is 8.4 nm in length (8) and fits well to the dimensions (8 nm) of the elongated central stalk of the negative-stained $\alpha_1\beta_0$ ATP synthase, indicating that the central stalk is made up by the subunits C, D (partly), and F.

**DISCUSSION**

The $\alpha_1\beta_0$ ATP synthase has been described as a chimeric enzyme combining the structural and functional features of F$_1$F$_0$ ATP synthases and V$_1$V$_0$ ATPases (4).
Thermus thermophilus 7) and the related A1A0 ATP synthase from M. mazei Go1. The A1 part and the low resolution structure of the hydrated A3B3CDF complex (D) from M. mazei Go1 at a 3.2-nm resolution (7). The black arrow shows the knoblike structures. The side view of the A3 complex (gold; C) and the envelope of the hydrated A2A3CDF complex derived from small-angle x-ray scattering data (green; D) from M. mazei Go1 are superimposed on the projection of the A1A0 ATP synthase from M. jannaschii, respectively.

The question that now arises is, which subunits of the A1A0 ATP synthase as isolated has nine subunits (A–I, K). Five of them form the A1 part and are assembled in the stoichiometry A3B3CDF (see above). The I and K subunits form the membrane domain, A0 (11, 12). Subunit I (70 kDa) is very similar to subunit a of the V1V0 ATPases with a hydrophilic N-terminal and a hydrophobic C-terminal domain. The C-terminus of subunit I is predicted to have seven transmembrane helices and is assumed to be functionally similar to subunit a of the V1V0 ATPases and F1F0 ATP synthases (3). The N-terminal domain is predicted to be highly α-helical and assumed to be the functional homolog of the soluble domain of peripheral stalk subunit b of F1F0 ATP synthases. Because only one of the peripheral stalks is clearly attached to the outside of the A0 domain, we conclude that the hydrophilic N terminus of subunit I emerges from the membrane-embedded A0 part and may go up along the side of A1 until the top of the A1 headpiece (Fig. 5). Whether the N-terminal domain might partly contribute to the cap on the top of the A1A0 molecule can only be speculated. In the presented average, the peripheral stalk (right) has a kinked structure in the lower part, giving this domain the flexibility to wrap around the A1 headpiece and ending up as the cap on the top (Fig. 3, B and C). Insertion and deletion of altered length in the so-called “tether” domain of the peripheral stalk subunit b of the Escherichia coli F1F0 ATP synthase, which is located above the membrane service, can be tolerated by the enzyme, indicating that this related connecting stalk has an inherent flexible structure (31). It has been suggested for the F1F0 ATP synthases that flexibility of the domain might allow reorientation of the stalk to act as a stator for rotation in one direction during ATP synthesis and in the opposite direction during ATP hydrolysis (31, 32).

Subunit K is a homolog of the F-type subunit c with two transmembrane helices. It consists of fused tandem repeats of transmembrane helices. It can be determined that subunit K has six membrane-spanning helices (27 kDa) but with only two active carboxylates per monomer (12), which are involved in ion conduction along the membrane. As in the case of the F-type ATP synthases (33, 34) and V-type ATPases (35), the K subunits (or c in the F- and V-type ATPases) are thought to form a ring, which belongs to the rotary element inside the A1A0 ATP synthase. As shown in Fig. 4, the bottom of the central CDF-stalk domain spans the upper center of the A0 domain, facilitating the direct contact of the rotary ele-
ements, which consists of an ensemble made from the central stalk (CDP domain) and a ring of hydrophobic K subunits in the Aβ membrane domain (21).

The second peripheral stalk appears to be connected to the collar domain and goes up to the A1 headpiece. Probable candidates for this stalk are the remaining Aββ-hydrophilic subunits H (12 kDa) and E (25 kDa) with the latter predicted to be highly α-helical (12). The modest contact area of this peripheral stalk with the A1 headpiece, which is also evident in electron micrographs of the related bacterial V1V0 ATPase from Cal
orator fumivorus (36), might be caused partially by stain accumulation. The top view projection of the rotated A1 complex (Fig. 4, panel D) shows a groove at the top of the Aββγ-hexamer in close neighborhood to this peripheral stalk. Such a groove-like feature may form a binding domain for the peripheral stalks.

In summary, the first two dimensional projection maps of the A1A0 ATP synthase from M. jannaschii presented provides the structural basis toward a fuller understanding of the mechanistic events occurring in this class of enzymes. The reconstruction at a 1.8-nm resolution shows similarities and diversities between the structural modules to the evolutionary-linked F1F0 ATP synthases and V1V0 ATPases, such as the catalytic Aβγ/γ1 headpiece and the central stalk domain. Although the existence of one (26, 37) or two (27) peripheral stalk(s) in the F1F0 ATP synthase is uncertain, these classes of ATPases/synthases might need at least one peripheral stalk as a stator that prevents the major hexameric arranged subunits (αββ or Aββγ) from following the rotation of the central stalk domain. Whether the visualized second peripheral stalk in the V1V0 ATPase and in the presented A1A0 ATP synthase might act as a regulatory domain in the A-type ATP synthase as described for the plant V ATPase (25) can now be addressed.
