Abstract

This review article describes epidemiology, clinical presentation, diagnostic workup and treatment options in adult non-cystic fibrosis (non-CF) bronchiectasis (widening of mainly small and medium sized bronchi as seen on chest-CT scan). We illustrate evidence from the literature with our own data retrieved from chart review, involving 236 adult patients with recurrent lower respiratory tract infections and HRCT-proven bronchiectasis, who visited the outpatient clinic of respiratory diseases of a large Dutch teaching hospital between 2000 and 2010.

Bronchiectasis (BE) can be described as a final common pathway of a vicious cycle of exaggerated bronchial inflammation, bacterial colonization and infection. BE may arise from several causes, headed by infection and immunodeficiency and is clinically characterized by a chronic, productive cough and infectious exacerbations. Once BE is diagnosed using high resolution CT scanning, a protocol-driven work-up to identify the underlying cause is recommended.

Non-medicinal treatment options are primarily directed at clearance of bronchial secretions, which can further be improved by inhalation of hyperosmolar agents. Antibiotic treatment of exacerbations is a cornerstone medicinal treatment in bronchiectasis management. Patients with frequent exacerbations can be considered for long-term low dose macrolide treatment, supported by robust evidence. Inhaled antibiotics might be beneficial in selected patients colonized with Pseudomonas aeruginosa. Important developments in the last decade include the introduction of international guidelines and the proposition of a validated scoring system for disease severity.

Bronchiectasis patients are encountered by physicians in diverse medical professions and the disease itself is still underdiagnosed. The authors aim to increase awareness of the condition and provide practical tools for diagnosis and treatment.

Introduction

Bronchiectasis – characterized by irreversible, pathologic dilatation of the small and medium-sized bronchi– is not a disease in its own right, but rather a final common pathway of a vicious cycle of inflammation, bacterial colonization and infection. A variety of respiratory and systemic diseases may be complicated by pathological bronchial dilatation, and therefore various medical specialists will be dealing with the condition in one way or the other. Although general availability of CT-scans has importantly contributed to higher case-finding rates, bronchiectasis is still considered an underdiagnosed condition. In this article, we address different signs and symptoms which can be clues to the diagnosis in order to facilitate recognition of the disease among non-pulmonary physicians. We further discuss our preferred diagnostic approach and give an overview of evidence- based treatment options.

Cystic Fibrosis (CF), an inherited multi-system disorder, is usually discussed separately and here we focus on non-CF bronchiectasis - hereafter referred to as ‘bronchiectasis’. The gold-standard for diagnosis has long been bronchography, until the introduction of high resolution CT scanning, the current standard diagnostic test. Due to the abundant amounts of purulent phlegm produced by affected individuals, bronchiectasis was considered offensive and also untreatable before the introduction of antimicrobial agents (1).

Around World War I bronchiectasis was common in the western world and it carried a poor prognosis: over 40% of all patients died of respiratory causes before the age of 40 (2-4). Improved socio-economic status, successful nationwide vaccination programmes for whooping cough and measles, and – most importantly – the availability of antibiotics reduced both incidence and mortality, in developed countries at least. Indeed, bronchiectasis became an ‘orphan disease’, as a result of which the focus of clinicians and researchers diverted away from this condition which was now considered rare with a relatively benign course. In spite of adequate antibiotic treatment, however, bronchiectasis still has the potential to cause substantial morbidity, including repeated lower respiratory infections complicated by hemoptysis, a disabling productive cough and shortness of breath, all of which importantly affect quality of life (2). Patients with bronchiectasis were found to spend more days in hospital and have higher annual medical care expenditure as compared to matched controls (3).

Recent epidemiological studies show a high incidence of bronchiectasis among New Zealand’s and Australia’s indigenous population and inhabitants of remote areas in Alaska (4). In the developed world estimated prevalence ranges from 0.42 per 100.000 in 18-34 year olds to 272 per 100.000 in those over 75 (5). Important developments in the last decade include the introduction of international guidelines, the proposition of a validated
scoring system for disease severity and the first large randomized trials on antibiotic maintenance treatment for those with frequent exacerbations, all of which will be discussed in this article (6-9).

We illustrate the evidence from the literature on the diagnosis and treatment of bronchiectasis using the experience gained in a large Dutch teaching hospital. Demographic, epidemiological and clinical data were collected from the entire, unselected, non-CF bronchiectasis cohort of the Alkmaar Medical Centre in 2010, for research purposes. Data were retrieved from chart review of all adult patients with recurrent lower respiratory tract infections and HRCT-proven non-CF bronchiectasis who visited the outpatient clinic of respiratory diseases of the Medical Centre Alkmaar at the time.

Pathophysiology

The mechanism of disease that eventually causes bronchiectasis is traditionally depicted as a vicious circle of exaggerated inflammation and bacterial colonization. Diverse stimuli, which can be either endogenic (such as ciliary defects) or exogenic (e.g. foreign body aspiration), may result in structural damage to the airways. This in turn allows for persistent bacterial colonization of the larger and medium-sized bronchi. The host inflammatory responses together with secreted bacterial toxins cause additional damage (hypersecretion, ciliary dysfunction and airway remodeling) which further weakens local resistance (10;11).

The immune response in bronchiectasis is mainly neutrophil driven and increased levels of chemokines and pro-inflammatory cytokines are found in the airways of affected individuals (12;13). High levels of proteases - toxic neutrophil products excreted on neutrophil activation - are present at the site of inflammation, causing release of pro-inflammatory cytokines and exerting proteolytic activity, thus causing even more damage to cells constituting the structure of the airways (14). T-cell infiltration, impaired macrophage phagocytosis, altered epithelial cell function and, more recently, deficiency of mannose binding lectine (MBL) have all been proposed as additional mechanisms responsible for an enhanced inflammatory response (11;15-18). A cycle of oxidative stress is also present, in which (mainly neutrophil derived-) reactive oxygen species cause damage to cells and the surrounding tissues and induce additional oxidative stress through activation of the inflammatory transcription factors nuclear factor-kappa B and activator protein-1 (19).

Causes

Bronchiectasis may arise from several different causes, headed by infection and immunodeficiency, mostly primary antibody deficiency syndromes (table 1). Due to successful prevention programmes for tuberculosis and childhood infections such as whooping cough and measles, post-infectious bronchiectasis tends to become less common in developed countries. In about half of patients, no underlying cause of permanent airway damage is found. Shoemark et al (20) found no causative factor in one third of their patients despite thorough systematic investigations in a tertiary referral centre. Other centres with multidisciplinary specialized bronchiectasis outpatient clinics with diagnostic protocols in place, report 40-50% idiopathic bronchiectasis in spite of an extensive workup (21-24).

Bronchiectasis is seen in 7-25% of patients with asthma or COPD, coinciding with more severe disease (25;26). While asthma has recently been considered a cause of bronchiectasis in the absence of other factors, the link between COPD and bronchiectasis has yet to be established (6).

The underlying cause for our cohort of patients is shown in table 1.

Table 1: Aetiology of bronchiectasis in 236 patients visiting the out-patient department of the Alkmaar Medical Centre as compared to possible causes for bronchiectasis as found in non-CF bronchiectasis phenotyping studies and clinical trials, n (total) = 1535 (20-22;24;55;60)

Clinical presentation and symptoms

The ‘typical’ patient with bronchiectasis is supposedly a middle-aged woman, who is a lifelong non-smoker – or at least, this is the profile of the majority of patients in bronchiectasis phenotyping studies (20-23;27;28). Our own data do not completely reflect this picture, as our patients were slightly older and, more frequently, smokers (table 2). This incongruence illustrates the varied clinical presentation of bronchiectasis patients in clinical practice. Bronchiectasis can just as well occur in the 80-yr-old male with frequent and virulent exacerbations of obstructive lung disease as in the 40-yr-old lady with rheumatoid arthritis visiting your practice with complaints of persisting cough. Severity of symptoms is different for each patient, but in general the course of the disease is highly variable, including nearly symptom-free periods interspersed with infectious exacerbations. The most persistent and often presenting symptom is a chronic productive cough, present in 96% of 103 patients referred to a pulmonary out-patient clinic, with the amount of sputum being among the main determinants of quality of life (2). Dyspnoea, fatigue and upper respiratory tract symptoms are encountered in 60-70% of patients. Pleuritic or musculoskeletal chest pain is present in 25-50 of patients and chest pain is often the reason for repetitive investigations at emergency departments. Exacerbations are characterized by an increase in symptoms and signs suggesting lower respiratory tract infection. Physical examination is often unremarkable except for the presence of crackles, mostly bilateral at the lower lobes. (27;28).

Diagnostic workup

Bronchiectasis ought to be considered in patients with a chronic productive cough and/or recurrent lower airway infections, especially when these symptoms are present in younger, non-smoking individuals. Hemoptysis, recurrent para-nasal sinus infections or successive sputum cultures positive for S aureus or P aeruginosa may also be clues leading to the diagnosis. In patients with asthma or COPD, bronchiectasis should be considered in case of frequent, slow resolving exacerbations, unstable or medication resistant asthma or severe symptoms despite limited exposure to smoking in patients diagnosed with COPD (6).

Key to the diagnosis are imaging studies using high resolution-CT. The chest CT protocol should be a spiral CT with 1 mm slices, able to detect pathology of larger and smaller airways, preferably with software allowing for reconstruction in different planes. In patients with bronchiectasis, the HRCT typically shows a distorted ratio (> 1,0) of the inner bronchial diameter as compared to the accompanying artery, and signs of bronchial dilatation: lack of tapering and increased visibility of small airways in the sub-pleural region (29) (fig 1). Plain chest X-rays show abnormalities in a large proportion of bronchiectasis patients (66% of our cohort), but changes are non-specific and a irremarkable chest X-ray does not rule out bronchiectasis.

Figure 1. CT scans of bronchiectasis three patients showing typical radiological features of bronchiectasis:

A. Increased bronchial diameter (signet ring sign) in a patient with allergic bronchopulmonary aspergillosis. B. Lack of tapering in a patient with COPD complicated by bronchiectasis. C. Increased visibility of small airways in the subpleural region in a patient with rheumatoid arthritis-associated bronchiectasis.
In symptomatic patients, the radiological finding of bronchiectasis should be followed by investigations to reveal the underlying cause. If a standardized protocol is used, the diagnostic yield may be enhanced, resulting not only in reduction of the proportion of patients diagnosed with ‘idiopathic’ bronchiectasis, but even in changing the treatment and the prognosis in up to 50% of patients (30;31). We use a diagnostic algorithm based on national and international guidelines (6;32;33) (fig 2). A standardized workup has been shown to reduce diagnostic delay which could last up to several years, especially in patients with underlying immune deficiency (34).

Localized bronchiectasis is usually indicative of a local mechanical cause (e.g. middle lobe syndrome) or post-infectious damage. The latter is even more plausible when a clear temporal relationship exists between an infectious episode and development of bronchiectasis-related symptoms. In other subjects, bronchiectasis can occur as a symptom of an already identified disease, such as rheumatoid arthritis or inflammatory bowel disease. In such cases we suggest to refrain from extensive investigations - or to only resort to additional testing if unexplained deteriorations occur. The same holds true for patients with asymptomatic bronchiectasis, as for instance can be seen in stable fibrosis (traction bronchiectasis).

Treatment options

When a specific disorder is found to cause bronchiectasis, disease management should primarily be directed at the underlying cause. This, for instance, applies to bronchiectasis due to allergic bronchopulmonary aspergillosis (ABPA) or common variable immune deficiency (CVID) both requiring their own treatment regimens.

Bronchiectasis management is aimed at preventing disease progression and improving quality of life by reducing symptoms and exacerbations. This includes treatment of exacerbations and optimal airway clearance, complemented with long-term antibiotic therapy (oral or nebulized) or surgery in selected cases. Many treatment options for non-CF bronchiectasis are derived from the treatment regimens developed for cystic fibrosis. At first, treatment modalities were simply extrapolated to non-CF patients, but in the last decade, treatment modalities have been studied for this specific group of patients, resulting in evidence-guided treatment recommendations. Sometimes these recommendations contradict those for CF, as is true for mucolytic treatment with recombinant human DNase (rhDNase). Routinely used in CF-treatment, rhDNase has been found of no benefit in one trial of non-CF bronchiectasis and harmful in another (35). No sufficient evidence is available to support the use of other mucolytics, such as acetylcysteine, in non-CF patients. Inhaled corticosteroids – although widely used by non-specialists in non-CF bronchiectasis patients – were only found effective in patients with underlying asthma. Current guidelines advise against routine use in non-CF bronchiectasis (6).

Nevertheless, it is worth mentioning that the pharmacological options described below - such as macrolides or inhaled hyperosmolar agents - have been approved by neither the US Food and Drug Authorization nor the European Drug regulators. Use is solely based on outcomes of clinical trials and international guidelines.

Management of infectious exacerbations

One of the cornerstones of bronchiectasis management is antibiotic treatment of infectious exacerbations. There are no randomized trials evaluating the effect or the duration of antibiotic treatment in bronchiectasis, but antibiotics are generally thought to reduce the time to recovery and to reduce symptoms. By convention, a 14-day-course of antimicrobials is prescribed, either intravenously or orally for exacerbations that last several days at least and are accompanied by increased sputum purulence, volume or reduced viscosity and increased cough, dyspnea and systemic upset such as fatigue or fever (6).

Preceding antibiotic treatment, sputum samples should be submitted for microbiological investigation and therapy should be directed at previously or newly isolated pathogens.

Physiotherapy

Most patients with bronchiectasis, especially those with excessive secretions, are offered physiotherapy. A customary physiotherapy program in the Netherlands would include one or more techniques directed at improved clearance of broncho-pulmonary secretions, combined with a pulmonary rehabilitation program to improve exercise tolerance. Forced expiratory manoeuvres as well as hand-held devices generating positive expiratory pressure (‘pep’-devices) such as Flutter™ or Acapella™ are used for optimal sputum clearance. A recent randomized trial, evaluating a similar approach, demonstrated a beneficial effect on exercise capacity, dyspnoea and fatigue in 85 patients (36).

A Cochrane review, evaluating the effect of physiotherapy-taught airway clearance techniques (ACT) as compared to no therapy or active coughing, demonstrated small improvements in sputum expectoration, lung function and health-related quality of life in 5 small and diverse studies, involving 51 patients (37). The choice of an ACT might as well be guided by patient preference, since there is no clear evidence in favor of any of the ACT’s available. A small randomized study in 30 patients showed improved exercise tolerance and
health related QOL with pulmonary rehabilitation in addition to ACT as compared to ACT alone (38).

**Inhalation of hyperosmolar agents**

Due to impaired mucociliary clearance, many patients with bronchiectasis suffer from mucus hypersecretion and retention, leading to dyspnea, chronic cough and increased susceptibility to infections. We frequently use inhalation of isotonic (0.9%) or hypertonic saline (6-7%) bid in addition to airway clearance techniques for optimal sputum evacuation. No evident benefit of nebulized hypertonic saline over isotonic saline has yet been demonstrated in the small studies available (39) and in our experience, patients report less discomfort in terms of wheezing or dyspnea when using the isotonic solution. Nevertheless, the inhalation process itself is often experienced as time consuming and inconvenient.

The hyperosmolar agent mannitol reduces exacerbations and improves lung function in cystic fibrosis (40). When administered as dry powder through a purpose-designed inhaler device, it is proposed as a less cumbersome alternative to saline inhalation. Several smaller or short-term studies on mannitol inhalations in bronchiectasis yield conflicting results in terms of sputum expectoration and quality of life (39). The sole large - yet slightly underpowered - long-term trial of 400 mg mannitol bd vs a non-therapeutic dose of 50 mg demonstrated that inhaled mannitol increases the time until first exacerbation in patients with bronchiectasis, without improving respiratory quality of life or reducing actual exacerbation rates (41). Mannitol is known for inducing bronchospasm. It is worth noting that ll participants in two large clinical trials were screened for mannitol tolerance at baseline and excluded when mannitol-induced bronchospasm was present (in 16% of all screened subjects). In the other participants mannitol inhalations were safe and well-tolerated (41;42). In the Netherlands, dry powder mannitol (Bronchitol™) is primarily used for optimizing sputum expectoration in cystic fibrosis patients and is not registered for use in other patient groups.

**Long-term antibiotic treatment**

Treatment with maintenance antibiotics in bronchiectasis can be directed at simply reducing the increased bacterial load, since chronic colonization has been found to coincide with enhanced inflammation and worse clinical outcome. In case of macrolides it is thought to dampen the exaggerated inflammatory response through multiple pathways (43).

**Macrolides**

Macrolides, because of their anti-bacterial and anti-inflammatory properties, have long been thought ideal to intervene in the vicious circle of infection and inflammation that underlies bronchiectasis. In three different clinical trials evaluating long-term oral macrolide treatment, exacerbation frequency was significantly reduced. All trials used different dosing regimes and there is an ongoing debate on which schedule should be used. Traditionally, many physicians use a dosing schedule equivalent to the CF treatment schedules consisting of azithromycin either 500 mg thrice weekly or 250 mg daily. Similar schedules were used in the BAT- and EMBRACE trials, as opposed to the Australian BLESS-trial which used erythromycin 400 mg twice daily (7-9). In CF patients macrolide antibiotics, and in particular azithromycin, tend to cumulate inside alveolar macrophages and as such have an extended half-life. Based on the pharmacokinetic properties of azithromycin in CF-patients - whose kinetics may differ considerably from those with non-CF - dose levels of 22-30 mg/kg/week divided by 1-7 dosing moments, are proposed (44). Lung function improvement and enhanced quality of life were most distinct in patients with frequent exacerbations. Recent COPD trials show a tendency to a higher yield of macrolide treatment in patients with more exacerbations (45). Although bronchiectasis guidelines consider patients with three or more exacerbations yearly and suffering from chronic symptoms to be candidates for this treatment type, no robust evidence is yet available to justify abstention from macrolide treatment in less frequent exacerbators (7-9).

Benefits of macrolide treatment come with a considerable increase in macrolide resistant pathogens, which demands judicious use of long-term macrolide therapy.

**Inhaled antibiotics**

Since the late nineties nebulized antibiotics for reducing airway bacterial load have been considered as a treatment option in bronchiectasis. Higher bacterial load is found to coincide with augmented systemic inflammation and an increased morbidity (46). Due to the favorable pharmacokinetic profile of inhaled substances, with minimal systemic drug delivery, systemic adverse effects are mild (47;48). Local, non-severe side effects are frequently encountered in clinical trials with inhaled antibiotics (49). Inhalation-induced bronchospasm could pose an extra challenge in clinical practice, but is usually overcome through inhalation of a short-acting beta-2 agonist prior to inhalation of antibiotics. Most randomized clinical trials evaluating inhaled antimicrobial agents included bronchiectasis patients colonized with Pseudomonas aerugiosa (PA) and used different types of antibiotics (colomycin, tobramycin), amikacin, or ciprofloxacin) (50-54). In addition, the three distinct trials (using aztreonam, gentimicin and ciprofloxacin), which did not specifically require PA
colonization for inclusion, in fact included many patients with PA-colonization at baseline (48-85%) (49;55;56). All trials demonstrated bacterial load reduction in the airways of actively treated patients, but this effect does not correspond consistently with improvement in clinical endpoints (57). The largest trial (n=500) of inhaled aztreonam in bronchiectasis patients - 85% of which PA colonized - failed to demonstrate reduced exacerbation rates or improved quality of life (49). Other authors report prolonged time to exacerbation and improved health related quality of life as secondary findings. The attractive safety profile and encouraging results in some studies have stimulated further research in this field and momentarily no less than seven trials are recruiting patients, most of which studying inhaled ciprofloxacin (58). Awaiting further evidence we think that nebulized antibiotics offer a reasonable alternative to oral treatment in selected patients colonized with P aeruginosa.

Other non-pharmacological options, such as surgery for localized disease and bronchial artery embolization in case of massive hemoptysis will not be discussed here in detail.

**Prognosis**

Although bronchiectasis can cause considerable morbidity, prognosis in terms of survival is favourable. The largest prospective study up until now found 62 deaths in 608 patients (10.2%) within 4 years, but the majority of deaths (81%) occurred above the age of 70 (59). Independent predictors of mortality were older age, low FEV-1, prior hospitalization and 3 or more exacerbations in the year prior to the study. The authors used these data to compile and validate a clinical prediction tool, the Bronchiectasis Severity Index, which divides patients in three risk groups (low/ intermediate/ high) in order to predict mortality, hospital admissions and exacerbations. This tool could be very useful in research settings in order to increase homogeneity of study populations. Its value for directing therapy in a clinical setting needs yet to be proven.

In conclusion, the broad range of diseases that cause or coincide with bronchiectasis, make it a frequently encountered entity in various medical specialisations. The authors hope that this article will renew awareness of this still underdiagnosed condition. Exciting new developments are the publication of high quality, randomised studies and new tools for patient selection which are important steps towards improving bronchiectasis management.
2.3 Gastro-intestinal investigation:

Symptoms suggestive of gastrointestinal reflux
In lung transplant patients

24h oesophageal pH monitoring
Referral to gastro-enterologist

2.4 Upper airway investigations:

Recurrent or chronic sinusitis
Chronic purulent minhorma

Referral to ENT specialist

2.4 2nd line immunological investigations**:

Antibody deficiency/abnormality in 1st line screening
Or: high clinical suspicion of immune deficiency
And/or: family history of immune deficiency
And/or: recurrent/persistent/serious/life threatening infections or infections involving multiple sites

T-cell function
B-cell function
Phagocyte function
Complement pathway assessment (CH-50 and AP-50)
MBL deficiency
Rarely: other immune compartments

2.5 Investigations to exclude Cystic Fibrosis:

Age at presentation < 40 years and no identified cause
And/or: Persistent isolation of S A reus in sputum
And/or: Features of malabsorption
And/or: Male primary infertility
And/or: Upper lobe bronchiectasis
And/or: History of childhood steatorrhea

Measurements of sweat chloride
+ CTFR mutation analysis

2.6 Tests of ciliary function**:

History of chronic LRT-problems or otitis media
And/or: Middle lobe bronchiectasis
And/or: Infertility or destocardia

Nasal nitric oxide (NO) measurement

Ciliary beat frequency/ pattern testing
+ Electron microscopy studies
