First Experimental Study of Photon Polarization in Radiative $B_\ell^0$ Decays

R. Aaij et al.\textsuperscript{*} (LHCb Collaboration)

(Received 10 September 2016; published 9 January 2017; corrected 28 February 2017)

The polarization of photons produced in radiative $B_\ell^0$ decays is studied for the first time. The data are recorded by the LHCb experiment in $p p$ collisions corresponding to an integrated luminosity of 3 fb\(^{-1}\) at center-of-mass energies of 7 and 8 TeV. A time-dependent analysis of the $B_\ell^0 \to \phi \gamma$ decay rate is conducted to determine the parameter $A^\Delta$, which is related to the ratio of right- over left-handed photon polarization amplitudes in $b \to s\gamma$ transitions. A value of $A^\Delta = -0.98^{+0.49+0.23}_{-0.52-0.20}$ is measured. This result is consistent with the standard model prediction within 2 standard deviations.

In the standard model (SM), photons emitted in $b \to s\gamma$ transitions are produced predominantly with a left-handed polarization, with a small right-handed component proportional to the ratio of the quark masses, $m_t/m_s$. In many extensions of the SM, the right-handed component can be enhanced, leading to observable effects in mixing-induced $CP$ asymmetries and time-dependent decay rates of radiative $B_\ell^0$ and $B^\ast_\ell^0$ decays [1,2]. Measurements of the time-dependent $CP$ asymmetries in radiative heavy meson decays have been performed by the BABAR and Belle Collaborations in the $B^\ast_\ell^0$ system only [3]. The production of polarized photons in $b \to s\gamma$ transitions was observed for the first time at LHCb by studying the up-down asymmetry in $B^+ \to K^+\pi^-\pi^+\gamma$ decays [4] (charge conjugation is implied throughout the text). In addition, angular observables in the $B^0 \to K^{\ast0}e^+e^-$ channel for dielectron invariant masses of less than 1 GeV/$c^2$ that are sensitive to the polarization of the virtual photon have also been measured at LHCb [5]. All of these measurements are found to be in agreement with the SM predictions.

This Letter reports the first experimental study of the photon polarization in radiative $B_\ell^0$ decays, determined from the time dependence of the rate of $B_\ell^0 \to \phi \gamma$ decays. The rate at which $B_\ell^0$ or $B^\ast_\ell^0$ mesons decay to a common final state that contains a photon, such as $\phi \gamma$, depends on the decay time $t$ and is proportional to

$$e^{-\Gamma_s t} \left\{ C \sinh (\Delta \Gamma_s t/2) - A^\Delta \sin (\Delta \Gamma_s t/2) + \zeta C \cos (\Delta m_t t) - \zeta S \sin (\Delta m_t t) \right\},$$

where $\Delta \Gamma_s$ and $\Delta m_s$ are the width and mass differences between the light and heavy $B_\ell^0$ mass eigenstates, $\Gamma_s$ is the mean decay width, and $\zeta$ takes the value +1 for an initial $B_\ell^0$ state and −1 for $B^\ast_\ell^0$. The coefficients $C$, $S$, and $A^\Delta$ are functions of the left- and right-handed photon polarization amplitudes [2]. The terms $C$ and $S$ can be measured only if the initial flavor is known: for an approximately equal mixture of $B_\ell^0$ and $B^\ast_\ell^0$ mesons, as used in this analysis, these terms cancel and the photon polarization affects only the parameter $A^\Delta$. This approach has the advantage that there is no need to determine the flavor of the $B_\ell^0$ candidates at production, which would considerably reduce the effective size of the data sample. Compared to the $B^0$ system, the $B_\ell^0$ system is unique in that the sizable width difference allows $A^\Delta$ to be measured. In the SM it can be parametrized as $A^\Delta = \sin (2\psi)$, where $\tan \psi \equiv |A(B_\ell^0 \to \phi \gamma)|/|A(B^\ast_\ell^0 \to \phi \gamma)|$ is the ratio of right- and left-handed photon amplitudes. The SM prediction is $A^\Delta_{SM} = 0.047 \pm 0.029$ [2].

This analysis is based on a data sample corresponding to 3 fb\(^{-1}\) of integrated luminosity, collected by the LHCb experiment in $p p$ collisions at center-of-mass energies of 7 and 8 TeV in 2011 and 2012, respectively. The LHCb detector is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, described in detail in Refs. [6,7]. Different types of charged hadrons are distinguished using information from two ring-imaging Cherenkov detectors. The online event selection is performed by a trigger, which consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage, which applies a full event reconstruction. Two trigger selections are defined with different photon and track momentum thresholds, depending on whether the hardware stage triggered on one of the tracks or on the photon. Samples of simulated events, produced with the software described in Refs. [8–13], are used to characterize signal and background contributions.

The decay mode $B^0 \to K^{\ast0}\gamma$, with $K^{\ast0} \to K^+\pi^-$, is used as a control channel. Since it is a flavor-specific decay, its decay-time distribution is not sensitive to the photon polarization. Throughout this Letter, $K^{\ast0}$ denotes...
Candidate $B^0 \to \phi \gamma$ and $B^0 \to K(892)^0 \gamma$ decays are reconstructed from a photon, and two oppositely charged tracks: two kaons to reconstruct $\phi \to K^+ K^−$ decays and a kaon and a pion to reconstruct $K(892)^0 \to K^+ \pi^−$ decays. The selection is designed to maximize the expected significance of the signal yield. Photons are reconstructed from energy deposits in the electromagnetic calorimeter and are required to have momentum transverse to the beam axis, $p_T$, larger than 1.7 or 2.0 GeV/$c$, depending on the trigger selection. Each charged particle is required to have a minimum $p_T$ of 0.5 GeV/$c$ and at least one of them must have $p_T$ larger than 3.0 or 4.2 GeV/$c$, depending on the trigger selection. The tracks are required to be inconsistent with originating from a primary $pp$ interaction vertex. The pion and kaon candidates are required to be identified by the particle identification system. The two tracks must meet at a common vertex and have an invariant mass within 15 MeV/$c^2$ of the known $\phi$ mass [14] for the signal mode, or within 100 MeV/$c^2$ of the known $K(892)^0$ mass for the control mode. Each $B^0_0$ or $B^0$ candidate is required to have $p_T$ larger than 3.0 GeV/$c$, and a reconstructed momentum vector consistent with originating from one and only one primary vertex. Background due to photons from $\pi^0$ decays is rejected by a dedicated algorithm [15]. In addition, the cosine of the helicity angle, defined as the angle between the positively charged hadron and the $B$ meson in the rest frame of the $\phi$ or $K(892)^0$ meson, is required to be less than 0.8.

A kinematic fit of the full decay chain is performed, imposing a constraint on the mass of the $B$ candidate. Its decay time is determined from the fitted four-momentum and flight distance from the primary vertex. The mass constraint improves the decay-time resolution and also ensures that it is not correlated with the reconstructed mass for the signal. Only candidates with decay times between 0.3 and 10 ps are retained.

The $B^0_0$ and $B^0$ signal yields are obtained from separate extended unbinned maximum likelihood fits to the $\phi \gamma$ and $K(892)^0 \gamma$ invariant mass distributions, shown in Fig. 1. The signal line shapes are described by modified Crystal Ball functions [16] with tails on both sides of the peak. The tail parameters are determined from simulation. Three background categories are considered: peaking, partially reconstructed, and combinatorial backgrounds. Peaking backgrounds are due to the misidentification of a final-state particle. All possible sources of misidentified tracks, as well as misidentification of a $\pi^0$ meson as a photon, are considered for the signal and control channels. Partially reconstructed backgrounds, in which one or more final-state particles are not reconstructed, are described with an ARGUS function [17] convolved with a Gaussian function to account for the mass resolution of the detector. The dominant contributions are decays with a missing pion or kaon, $B \to K \pi \pi^0 X$, and $B^0 \to K(892)^0 \eta$. All shape parameters for the peaking and partially reconstructed backgrounds are fixed from simulation. The ratios of the yields of peaking backgrounds to signal are fixed using previous measurements [14,18]. A first-order polynomial is used to describe the combinatorial background. The signal yields are $4072 \pm 112$ and $24808 \pm 321$ for the $B^0_0 \to \phi \gamma$ and $B^0 \to K(892)^0 \gamma$ decays, where the uncertainties are statistical only.

The mass fits are used to assign each candidate of the $B^0_0 \to \phi \gamma$ and $B^0 \to K(892)^0 \gamma$ samples a signal weight to subtract the backgrounds [19]. An unbinned maximum likelihood fit of the weighted decay-time distributions [20] is then performed simultaneously on the $B^0_0 \to \phi \gamma$ and $B^0 \to K(892)^0 \gamma$ samples. The signal probability density function (PDF) is defined from the product of the decay-time-dependent signal rate $P(t)$ and the efficiency $\epsilon(t)$, convolved with the resolution.

For $B^0_0 \to \phi \gamma$, Eq. (1) reduces to

$$P(t) \propto e^{-\Gamma_s t} \{\cosh (\Delta \Gamma_s t/2) - A^\Delta \sinh (\Delta \Gamma_s t/2)\},$$

when summing over the initial $B^0_0$ and $B^0_0$ states. The $B^0_0$ and $B^0_0$ production rates are assumed to be equal, given that their measured asymmetries [21] are found to have a negligible effect on the measurement of $A^\Delta$. For $B^0 \to K(892)^0 \gamma$, the decay-time-dependent signal rate is a single exponential function, $P(t) \propto e^{-\Gamma_s t}$. The physics parameters $\tau_{\phi^0}, \Gamma_s$, and $\Delta \Gamma_s$ are constrained to the averages from Ref. [3]: $\tau_{\phi^0} = 1.520 \pm 0.004$ ps, $\Gamma_s = 0.6643 \pm 0.0020$ ps$^{-1}$, and $\Delta \Gamma_s = 0.083 \pm 0.006$ ps$^{-1}$. The correlation

![FIG. 1. Fits to the invariant mass distributions of the $B^0_0$ (top) and $B^0_0$ (bottom) candidates.](image-url)
of $-0.239$ between the uncertainties on $\Gamma_s$ and $\Delta\Gamma_s$ is taken into account.

To ensure that the simulation reproduces the decay-time resolution, additional control samples of $B^0_s \rightarrow J/\psi \phi$ and $B^0 \rightarrow J/\psi K^{*0}$ decays are used, where the $J/\psi$ meson is reconstructed from a pair of oppositely charged muons. Selections mimicking those of $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$, treating the $J/\psi$ meson as a photon, are applied. The distributions of the difference in position between the reconstructed $J/\psi$ mesons and $\phi$ or $K^{*0}$ vertices are measured in data and simulation and found to be in agreement. The decay-time-dependent resolution functions are then determined from the simulation. The decay-time resolution is small compared to the $B$-hadron lifetimes, and similar for $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$.

The decay-time-dependent efficiency is parametrized as

$$e(t) = e^{-\alpha t} \frac{[a(t-t_0)]^n}{1 + [a(t-t_0)]^n} \quad \text{for} \quad t \geq t_0,$$

where the parameters $a$ and $n$ describe the curvature of the efficiency function at low decay times, $t_0$ is the decay time below which the efficiency function is zero, and $\alpha$ describes the decrease of the efficiency at high decay times. Large simulated samples of $B^0 \rightarrow \phi\gamma$ or $B^0 \rightarrow K^{*0}\gamma$ decays are used to validate this parametrization. The signal PDF is found to describe the reconstructed decay-time distribution of selected simulated candidates over the full decay-time range. The $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$ decay-time-dependent efficiency parameters are found to be similar. In a simultaneous fit of both simulation samples, requiring the parameters $a$ and $n$ to be the same for both channels does not change the quality of the fit. To assess whether the simulation reproduces the decay-time-dependent efficiency, the $B^0 \rightarrow K^{*0}\gamma$ data sample alone is used to fit $\tau_{\psi\phi}$, fixing in this case all the efficiency parameters to those from the simulation. The fitted value of $\tau_{\psi\phi}$ is $1.524 \pm 0.013$ ps, where the uncertainty is statistical only, in agreement with the world average value [3]. In the simultaneous fit to the data, the parameters $a$ and $n$ are required to be the same for both channels and fixed to their values in the simulation. For $t_0$ and $\alpha$, a global offset, the same for both channels, is allowed between data and the simulation.

Pseudoexperiments are used to validate the overall fit procedure. For each pseudoexperiment, samples of $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$ candidates are generated, including both signal and background contributions. The expected yields are taken from the fit to the data, as is the signal mass shape. Background events are generated according to the mass and decay-time PDFs determined from fits to samples of events generated with the full LHCb simulation. For each pseudoexperiment, the mass fits to the $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$ samples are performed, followed by the decay-time fit to the background-subtracted samples. The procedure is tested in samples of pseudoexperiments generated with different values of $A^\Delta$. No bias on the average fitted value of $A^\Delta$ is observed. Statistical uncertainties are found to be underestimated by an amount that depends on $A^\Delta$; the effect is $5.8\%$ for the value seen in data and is accounted for in the results below.

The $B^0 \rightarrow K^{*0}\gamma$ and $B^0_s \rightarrow \phi\gamma$ background-subtracted decay-time distributions and the corresponding fit projections, including the ones for the central value of the SM prediction for $A^\Delta$, are shown in Fig. 2. The fitted value of $A^\Delta$ is $-0.98^{+0.46}_{-0.52}$. The statistical uncertainty includes a contribution due to the uncertainties on the physics parameters $\tau_{\psi\phi}$, $\Gamma_s$, and $\Delta\Gamma_s$, which is estimated to account for $+0.10_{-0.17}$.

In an alternative approach, $A^\Delta$ is calculated from the ratio of the yields of $B^0_s \rightarrow \phi\gamma$ and $B^0 \rightarrow K^{*0}\gamma$ in bins of decay time. Based on a study of pseudoexperiments, the binning scheme is designed to have the same number of events in each bin, thereby optimizing the overall
sensitivity to $A^\Delta$. Decay-time-dependent efficiency and resolution effects are taken into account by calculating correction factors in each bin before fitting for $A^\Delta$. Pseudoexperiments are used to validate this approach and to test its sensitivity, which is found to be equivalent to that of the baseline procedure. The fit to the data is shown in Fig. 3, along with the expected distribution for the central value of the SM prediction [2] is also shown.

The dominant systematic uncertainty comes from the background subtraction. It is evaluated to be $+0.19 -0.20$ and includes contributions from potential correlations between the reconstructed mass and decay time for the backgrounds ($\pm 0.15$), uncertainties on the peaking background yields ($\pm 0.02$), and the models used in the mass fit. The latter is assessed by the use of alternative models: an asymmetric Apollonios function [22] for the signal ($\pm 0.03$), an exponential for the combinatorial background ($\pm 0.07$), and several shape variations for the most relevant partially reconstructed backgrounds ($\pm 0.10$). The systematic uncertainty due to the limited size of the simulation samples used to assess the decay-time-dependent efficiency is $+0.12 -0.05$. The uncertainties related to the decay-time resolution are negligible. The sum in quadrature of these systematic uncertainties is $+0.23 -0.20$.

In summary, the polarization parameter $A^\Delta$ is measured in the first time-dependent analysis of a radiative $B^0_\gamma$ decay, using a data sample corresponding to an integrated luminosity of 3 fb$^{-1}$ collected by the LHCb experiment. This parameter is related to the ratio of right- over left-handed photon polarization amplitudes in $b \to s\gamma$ transitions. More than 4000 $B^0_\gamma \to \phi\gamma$ decays are reconstructed. The decay-time-dependent efficiency is calibrated with a control sample of $B^0 \to K^{*0}\gamma$ decays that is 6 times larger. From an unbinned simultaneous fit to the $B^0_\gamma \to \phi\gamma$ and $B^0 \to K^{*0}\gamma$ data samples, a value of

$$A^\Delta = -0.98^{+0.46}_{-0.52} \pm 0.23$$

is measured, where the first uncertainty is statistical and the second systematic. The result is compatible with the SM expectation, $A^\Delta_{BM} = 0.047^{+0.029}_{-0.025}$ [2], within 2 standard deviations.

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes.
