Received March 4, 2009; accepted May 7, 2009; published online May 19, 2009

Purpose. To develop a new minimal-stress model for intranasal administration in freely moving rats and to evaluate in this model the brain distribution of acetaminophen following intranasal versus intravenous administration.

Methods. Male Wistar rats received one intranasal cannula, an intra-cerebral microdialysis probe, and two blood cannulas for drug administration and serial blood sampling respectively. To evaluate this novel model, the following experiments were conducted. 1) Evans Blue was administered to verify the selectivity of intranasal exposure. 2) During a 1 min infusion 10, 20, or 40 μl saline was administered intranasally or 250 μl intravenously. Corticosterone plasma concentrations over time were compared as biomarkers for stress. 3) 200 μg of the model drug acetaminophen was given in identical setup and plasma, and brain pharmacokinetics were determined.

Results. In 96% of the rats, only the targeted nasal cavity was deeply colored. Corticosterone plasma concentrations were not influenced, neither by route nor volume of administration. Pharmacokinetics of acetaminophen were identical after intravenous and intranasal administration, although the Cmax in microdialysates was reached a little earlier following intranasal administration.

Conclusion. A new minimal-stress model for intranasal administration in freely moving rats has been successfully developed and allows direct comparison with intravenous administration.

KEY WORDS: acetaminophen; brain; intranasal infusion; microdialysis; pharmacokinetics.

INTRODUCTION

Targeting the central nervous system (CNS) by intranasal delivery is a promising alternative for oral or parenteral administration, and is investigated to directly target the brain, thereby increasing CNS target site bioavailability and the efficacy of CNS drugs (1–3). Little is known however on the distribution of CNS drugs into the target site, i.e. the extracellular fluid (ECF) surrounding the pharmacologic receptors in brain tissue, following intranasal administration.

Current pharmacokinetic-pharmacodynamic (PK-PD) studies after intranasal administration in small laboratory animals are performed with anaesthetized animals, whether or not in combination with complete isolation of the nasal cavity and a cannulated trachea to aid breathing (4–7). Other research is based upon restrained animals(8). All methods currently used have major influence on physiology (i.e. blood flow, nasal immunology, mucociliary clearance, nasal cycle, airflow dynamics, and stress), which all play important roles in the PK and/or PD of compounds (9–17). Therefore, this methodology complicates quantification of PK-PD endpoints and consequently the extrapolation to the in-vivo human situation.

To meet the demands for animal PK/biomarker models and nasal administration techniques, which allow better interpretation and translation of PK-PD parameters from animal to man, a new animal model is needed that allows drug administration under minimal stress conditions in freely moving animals.

The objective of this study was to develop and validate a new preclinical, refined minimal stress animal model, in which we can administer compounds intranasally and intravenously, while blood- and brain ECF samples can be taken over time, to obtain PK-PD parameters in plasma and brain of freely moving animals. After comparing the size of nasal cavities, the highly vascular olfactory epithelium ratios, and cost-considerations of eight different species, as described by Ugwoke et al. (17), we focused on the rat as animal of choice. An intranasal cannula was manufactured and implanted together with an intracerebral microdialysis probe. Also the animals received two blood cannulas for drug administration and serial blood sampling respectively. The intranasal site of administration needed to be substantiated by a staining study. Through corticosterone measurements and comparison with literature, any stress effects during our experimental- and administration techniques had to be excluded (18). Then, our
model had to be validated, which was done by the administration of a model compound and comparing the pharmacokinetics between the groups. Acetaminophen was used for its linear plasma and BBB transport kinetics (19-23). P-glycoprotein (P-gp) efflux did not have to be considered since acetaminophen is no P-gp substrate (20-22). To explain concentration time profiles and include both intraindividual and interindividual variability, pharmacokinetic modelling was used to calculate population parameter estimates of blood- and brain PK.

MATERIALS AND METHODS

Surgery and Methods

All animal procedures were performed in accordance with Dutch laws on animal experimentation. The study protocol was approved by the Animal Ethics Committee of Leiden University (UDEC nr. 6023 and 6132). Male Wistar WU rats (245±18 g, Charles River, The Netherlands), n=89, were housed in groups for 7–13 days (Animal Facilities, Gorlaeus Laboratoria, Leiden, The Netherlands), under standard environmental conditions (Ambient temperature 21°C; humidity 60%; 12/12 h light, background noise, daily handled), with ad libitum access to food (Laboratory chow, Hope Farms, Woerden, The Netherlands) and acidified water. Between surgery and experiments, the animals were kept individually in Makrolon type three cages for 7 days to recover from the surgical procedures.

All surgical procedures were performed under complete anaesthesia with subcutaneous administration of 0.1 ml/100 g Ketanest (ketamine base 25 mg/ml, Pfizer B.V., Capelle a/d IJssel, the Netherlands), and 0.01–0.017 ml/100 g Domitor (medetomidine hydrochloride 1 mg/ml, Pfizer Animal Health B.V. Capelle a/d IJssel, The Netherlands). Body temperature was maintained at 37°C by an electric heating pad. All cannulas were disinfected with 0.1% benzalkoniumchloride.

The animals were chronically instrumented with a CMA/12 microdialysis guide (Aurora Borealis Control, Schoonebeek, The Netherlands) in the olfactory bulb. The guide was handled, with

\[
\text{CMA/Microdialysis, Stockholm, Sweden}
\]

tunnelled subcutaneously to the back of the head. The end was melted shut to prevent infection. Consequently, the animals received two cannulas. To obtain blood samples, 3 cm of ID 0.28 mm cannula (SIMS Portex LTD, England) was inserted in the femoral artery, connected to 16 cm x 0.58 mm internal diameter (ID) cannula (Portex Fine Bore polythene tubing Smiths Industries, Kent England.). For drug administration, 4 cm of ID 0.58 mm cannula was inserted in the femoral vein, and 16 cm of ID 0.58 mm cannula was, similar to the sampling cannula, led subcutaneously to the back of the head where it was fixated with a rubber ring.

After the surgery the animals received 0.03 ml Temgesic® intramuscular (Schering-Plough, The Netherlands) and 0.3 ml Ampicillan® (Alfasan B.V. Woerden) subcutaneously. After 6 days the guide was replaced by the microdialysis probe (CMA/12, 4 mm Polycarbonate membrane, cut-off 20 kD) at a pre-experiment interval of 24±1 h.

In the corticosterone study, a control group of seven rats received 500 µl intravenously administered saline (B. Braun Melsungen AG, Melsungen, Germany) during a 1-minute infusion with an automated pump (Harvard apparatus 22, model 55–2222, Holliston, MA, USA). The experimental groups received 10, 20, or 40 µl of saline intranasally (n=8, 10, and 9 respectively). Blood samples of 200 µl were taken from the arterial cannula at t=0 (blank), 5, 10, 20, 35, 60, 90, 120, 150, and 180 min, shaken in heparin (10 IE) coated eppendorfcups (Sarstedt, Nümbrecht, Germany), and temporarily stored on ice. After the experiment the samples were centrifuged for 15 min at 5,000 rpm and stored at −20°C.

Using the aforementioned automated pump, in the acetaminophen study the control group received a dose of 200 µg acetaminophen (Leiden University Medical Center Pharmacy, Leiden, The Netherlands) in 250 µl saline intravenously in 30 s. In the experimental groups, 200 µg acetaminophen in 20, 30, or 40 µl saline was administered intranasally during a 1 min infusion. Start and duration of infusion was corrected for internal volume of the tubing so that infusion started at t=0 min. Blood samples of 200 µl were taken from the arterial cannula at t=0 (blank), 5, 10, 20, 35, 60, 90, 120, 150, and 180 min, and temporarily stored in heparin (10 IE) coated eppendorfcups (Sarstedt, Nümbrecht, Germany), and temporarily stored on ice. After the experiment the samples were centrifuged for 15 min at 5,000 rpm and stored at −20°C.

Microdialysis perfusion fluid (PF) was prepared (24), consisting of phosphate buffer (2 mM, pH 7.4), containing 145 mM sodium, 2.7 mM potassium, 1.2 mM calcium, 1.0 mM magnesium, 150 mM chloride, and 0.2 mM ascorbate, which was filtered, stored in glass vials (−20°C), and sonified before use. Tubing (1.2 µl/100 mm FEP-tubing CMA/Microdialysis AB, Stockholm, Sweden) was connected with tubing adapters (CMA/Microdialysis, Stockholm, Sweden) to the microdialysis probe’s inlet and outlet. Microdialysis vials were preweighed and placed in a cooled fraction collector (Univentor 820 Microsampler, Antec, Netherlands) to collect the microdialysate samples. Microdialysis probes were continuously flushed with PF (2 µl/min, Bee-Hive, Bioanalytical Systems Inc. W-Lafayette, USA), and 10 min interval samples were collected between t=−1 h to t=1 h, followed by 20 min

![Image](https://via.placeholder.com/150)

interval samples until $t=3$ h. After sample collection, vials were weighed to determine true probe perfusion rate (a maximal deviation of 5% was allowed for the sample to be included in the data), and stored at $-80^\circ$C.

In 27 rats of the intranasal groups, 30 µl 0.5% Evan’s blue was administered in 30 s at the end of the experiments. 10 to 15 min later, the animals were sacrificed with an overdose of Nembutal (Ceva Sante Animale, Naaldwijk, The Netherlands). The nose tip, nasal cavities, brain, mouth, lungs, and intestines were visually examined for blue coloring and scored on a scale; 3, 2, 1, and 0, representing full, medium, light, and no coloring respectively.

**Analysis**

For the plasma corticosterone (CORT) concentrations, a commercially available $^{125}$I-corticosterone Radio Immunoassay (RIA) was used (ImmunoChem™ Double Antibody Corticosterone $^{125}$I RIA kit, MP Biomedicals, Orangeburg, NY, USA), according to the instructions of the manufacturer. Data acquisition was performed on a Gamma Scintillation Counter (Minaxi 5000 series, Packard). Concentrations were calculated using R 2.5.0 (The R Foundation for Statistical Computing, Vienna, Austria). Data exceeding 1.5 times the interquartile range was excluded from the dataset. Geometric means of the CORT concentrations over time. Data analysis, statistical analysis, excluded from the dataset before plotting geometric mean concentrations over time. Data analysis, statistical analysis, and plotting was performed using Microsoft® Office Excel 2003 (Microsoft Corporation, USA) and OriginPro® 7.5 (OriginLab Corporation, Northhampton, MA, USA).

Heteroscedasticity was eliminated before executing a single factor ANOVA on every time point (25,26). When $p<0.05$, a Student T-test (one-tailed homoscedastic) was performed between the individual groups per time point. Areas Under the Curve (AUC) were calculated by the trapezoidal rule and microdialysis AUC’s were corrected for in vitro recovery. AUC’s were plotted, and tested for differences between groups by single factor ANOVA. The absolute recovery was calculated by dividing the plasma AUC after IN administration by the plasma AUC after IV administration.

Nonlinear mixed effect modelling (NONMEM 6.2, run in the PSN module (27) under Windows XP Professional 2002 (service pack3) on an Intel Pentium D CPU3.2 GHz processor) was used to model the pharmacokinetic parameters clearance and volume of distribution. 1-, 2- and 3-compartment models were entered in various subroutines in NONMEM for the experiments with acetaminophen, and identified by likelihood ratio test ($p<0.05$; decrease in objective function value of 3.84 points), pharmacokinetic parameter estimate endpoint, and goodness-of-fit plots. The interindividual variability of the blood PK model was assumed log-linear and optimized by taking possible correlation between parameters into account, and by testing the intraindividual variability through an additive error model versus a constant coefficient of variation model. The individual parameter estimates of the blood PK model allowed estimation of intercompartimental clearance and volume of distribution in the brain compartment. Population parameter estimates were assumed to be normally distributed, and transferred into a clean glass tube; 150 µl 1 M Sodiumacetate was added, and after vortexing, injected into the HPLC-ECD. 20 µl of the microdialysate samples was vortexed with 20 µl IS and directly injected into the HPLC-ECD system.

The analytical equipment consisted of a LC-10 AD pump (Shimadzu, ‘s Hertogenbosch, The Netherlands), a Waters 717plus Autosampler (Waters, Etten-Leur, The Netherlands), a pulse damper (Antec Leyden, Zoeterwoude, The Netherlands), a C18 ODS Ultrasound 5 µm column (4.6 mm x 15 cm) with C18 refill guard column (Alltech Netherlands B. V., Ridderkerk, The Netherlands), an electrochemical amperometric detector (DECADE, software version 3.02, Antec Leyden B.V., Zoeterwoude, The Netherlands), a VT-03 electrochemical flow cell, 25 µm spacer, and in situ AG/AgCl (ISAAC) reference electrode (filled with a saturated potassiumchloride solution) operating in DC mode. The mobile phase (MP) consisted of a 85% Phosphate buffer (96.4% 1.0 M NaH2PO4, 3.6% 1.0 M Na2HPO4, diluted with MQ to 50 mM Phosphate buffer, and OSA was added to obtain 2 mM OSA), 15% MeOH and 100 mg/l EDTA. MP was filtered through a 0.2 µm nylon filter membrane (Alltech Netherlands B.V., Ridderkerk, The Netherlands).

Data acquisition and processing was performed using Empower® data acquisition software (Waters, Etten-Leur, The Netherlands). For constructing the calibration curve, linear regression analysis was applied using weight factor $1/(y)^2$. Data exceeding 1.5 times the interquartile range were excluded from the dataset before plotting geometric mean concentrations over time. Data analysis, statistical analysis, and plotting was performed using Microsoft® Office Excel 2003 (Microsoft Corporation, USA) and OriginPro® 7.5 (OriginLab Corporation, Northhampton, MA, USA).

Heteroscedasticity was eliminated before executing a single factor ANOVA on every time point (25,26). When $p<0.05$, a Student T-test (one-tailed homoscedastic) was performed between the individual groups per time point. Areas Under the Curve (AUC) were calculated by the trapezoidal rule and microdialysis AUC’s were corrected for in vitro recovery. AUC’s were plotted, and tested for differences between groups by single factor ANOVA. The absolute recovery was calculated by dividing the plasma AUC after IN administration by the plasma AUC after IV administration.

The individual parameter estimates of the blood PK model allowed estimation of intercompartimental clearance and volume of distribution in the brain compartment. Population parameter estimates were assumed to be normally distributed, and...
considered equal when the 95% confidence intervals of the parameter estimates overlap (1.96 times the standard error).

RESULTS

Evan’s Blue

Of the 27 rats that had received Evans Blue through the intranasal probe in the right nasal cavity, one had a broken septum and was excluded in the determination of the nasal coloration. One animal experienced blocking of the intranasal probe, thereby decreasing the amount of Evan’s Blue reaching the right nasal cavity. Full coloration of the right nasal cavity was observed in 96% of the animals. The nose tip, tongue, palate and intestine were light colored in 81%, 89%, 93%, and 79% of the animals respectively. In the left nasal cavity 67% was not colored. In 96% of the animals the lungs as well as the olfactory bulb were not colored. Table I shows all the acquired data.

show significant differences (p-values>0.23) over the time period of 180 min (Fig. 2).

Acetaminophen as Model Compound

The log-normal geometric mean-time profiles of the concentrations in plasma after administration of acetaminophen (Fig. 3) showed the same profiles for all groups. At t=10 min there were differences between the groups when tested IV vs 30 µl, 20 µl vs 30 µl, and 20 µl vs 40 µl (P-values are 0.04, 0.00, and 0.02 respectively). At t=180 differences were found between IV and 20 µl, 20 µl vs 30 µl, and 20 µl vs 40 µl (P-values were 0.00, 0.04, and 0.02 respectively). Areas under the curve (AUC) in plasma with their standard error of the means were calculated (Fig. 4): 10.5±0.7, 11.6±0.6, 8.8±0.9, and 9.6±0.8 (µg*min)/ml for IV, 20, 30, and 40 µl IN administration respectively. No statistically significant differences between the groups were found (P=0.07).

After measuring and plotting the geometric mean (± S.E. M., Fig. 3) of acetaminophen brain microdialysate concentrations over time, single factor ANOVA revealed a differ-

Fig. 2. Concentration-time profiles of corticosterone (geometric mean ± S.E.M.) in plasma after intranasal administration of different volumes of saline (IN-20, -30, and -40 µl), compared to intravenous (IV-500 µl) administration. Single factor ANOVA proves no differences between the groups (p>0.23). n=9, 9, 8, and 6 for the IV, IN-20 µl, IN-30 µl, and IN-40 µl groups respectively.

Fig. 3. Concentration-time profiles (geometric means ± S.E.M.) of acetaminophen in plasma and brain microdialysate after intranasal (IN) administration of 200 µg acetaminophen in different volumes, compared to intravenous (IV) administration. At t=10 min concentrations in plasma (solid line) differed when tested IV vs. IN-30 µl, IN-20 µl vs. IN-30 µl, and IN-20 µl vs. IN-40 µl (p=0.04, 0.00, and 0.02 respectively). At t=180 differences were found between IV and 20 µl, 20 µl vs 30 µl, and 20 µl vs 40 µl (p=0.00, 0.04 and 0.02 respectively). In the brain microdialysates (dotted line) differences were found at t= 5, 35, and 90 min (p=0.00, 0.04, and 0.03 respectively).
ence in profiles at t=5, 35 and 90 min (P-values were 0.00, 0.04 and 0.03 respectively). The maximal brain microdialysate acetaminophen concentration was reached earlier after intravenous administration. Microdialysis in vitro recovery was 40%. The mean AUCs ± S.E.M. of the brain concentrations were 2.54±0.31 (µg*min)/ml and 2.55±0.44 (µg*min)/ml for the control group and experimental group receiving 20 µl solution respectively and did not differ (Fig. 4, p=0.98). The absolute recovery of acetaminophen was 95%.

After comparing several models, a 2-compartment model with the brain compartment as an effect compartment, constant coefficient of variation for intraindividual variability and correlation between the clearance and volume of distribution of compartment 1 and 3 proved to fit the data best for both the experimental and the control study. Estimating interindividual variability on clearance and volume of distribution in effect compartment 2 did only improve the model (decrease in objective function value>3.84) of intranasal administration. Parameter estimates with their 95% confidence interval aquired from NONMEM are listed in Table II.

**DISCUSSION**

The aim of this study was to develop and validate a new preclinical, refined minimal stress animal model, in which we can administer compounds intranasally and intravenously, with blood- and brain ECF samples to be taken over time. Our results indicate that IN administration in freely moving rats does not induce stress, while for the model compound acetaminophen it was observed that the pharmacokinetics following IN and IV administration were similar.

**Evan’s Blue**

Evan’s Blue is a dye with a high affinity for albumin which is present in nasal mucosa. Besides the expected full colouration of the targeted nasal cavity, 93% of the animals showed light coloration of the palate caused by leakage through the nasopalatine duct that connects the nose and mouth. This might be an indication for buccal absorption in rats, which should be considered in the PK and extrapolation of data to clinical situations, since in humans the nasopalatine duct does not extend to the mouth. However, due to its role, in cooperation with the vomeronasal organ, in food recognition, sex recognition, and courtship we found it not advisable to close the nasopalatine duct (28). Also, after the 10 min following Evans Blue administration a small part was swallowed, which could indicate the possibility of partial oral uptake after intranasal administration. This can be caused by passive leakage to the oesophagus and/or active sweeping by the cilia in the nose. Since rats are obligate nose breathers (29) this obviously cannot be prevented in freely moving animals. The concentration-time curves of acetaminophen however, excluded substantial uptake of compound through oral absorption. Use of other (more viscous) formulations could possibly eliminate this problem in future research.

Data represented are population parameter estimates (θ) with their interindividual variability (η²) and the population intraindividual variability (ε²) with their 95% confidence interval after intravenous (IV) or intranasal (IN) administration of 200 mg acetaminophen. Parameters of the first central compartment are clearance (CL1) and volume of distribution (V1). For the second peripheral compartment clearance (CL2) and volume of distribution (V2) were determined, as well as the absorption rate constant (KA) after IN administration. In the brain the intercompartmental clearance(Q) and volume of distribution (V3) were estimated. Parameter estimates that differ between the studies are denoted with *.
Corticosterone

In our study, the CORT data show no influence of administration techniques, nor of volume of administration. Cano et al. (18) performed a circadian rhythm study concerning the CORT concentrations in Wistar rats during high-fat induced stress and compared it to a normally fed control group. In that study, plasma concentrations of CORT were found to be 283±35 ng/ml (means ± S.E.M.) in the control group, with an amplitude of 97±11 ng/ml, versus 456±42 ng/ml in the experimental group, showing a significant difference compared to the control group (p<0.01). Also, in that study, CORT concentrations were roughly 200 ng/ml straight after onset of the light phase, indicating higher basal concentrations when compared with our experiments 166±14 ng/ml (basal average ± S.E.M.). Additionally, Perello et al. (30) discovered in individually housed Wistar rats, after decapitation under conditions of minimal stress after the onset of the light phase, basal concentrations of 363±35 ng/ml (means ± S.E.M.) in animals. This was significantly higher when compared to their group-housed animals (206±32) and to our individually housed freely moving animals. Perello et al. (30) stated their CORT concentrations to be low when compared to restraining studies and bacterial lipopolysaccharide injection. In our freely moving animals, we find no evidence that stress levels are increased due to our handling techniques or experiments, moreover, when compared to aforementioned studies, we have less CORT release indicating less stress.

Acetaminophen

In principle, differences in the concentration time profiles in both plasma and brain data can be explained by the absorption phase over the nasal epithelium versus IV administration, as well as by the difference in infusion time. Equal plasma AUCs indicate that the same amount of drug as IV is absorbed after IN administration. Although differences are found when testing data per time point, the comparison of the concentration-time profiles with NONMEM show no differences in parameter estimates, except for V2. Adding interindividual variability for V2 in the IV model did not increase the predictability and was therefore left out of the model, but this can cause the difference in the population estimates for V2 since adding interindividual variability did improve the IN model. The individual- and population estimates described the data well. We can consider the free drug concentrations in the ECF in terms of intercompartmental clearance (Q3) and V3, which gives us information on the blood-brain-barrier transport and whether direct transport from the nasal epithelium into the brain could be an issue. Since the plasma pharmacokinetics after IV and IN administration are similar, increased CNS target site bioavailability after IN administration should result in increased brain concentrations after IN administration compared to IV administration, which is not the case.

Acetaminophen is subject to metabolism by P450, that is highly present in the nasal epithelium (31), but this did not influence the PK of acetaminophen following intranasal administration relative to that following intravenous dosing. Furthermore, we found no evidence of substantial buccal or oral absorption in the concentration-time profiles of acetaminophen. The population estimates of the brain showed no differences in intercompartmental clearance, volume of distribution, interindividual- or intra-individual variability.

CONCLUSIONS

The animals showed clear coloration in the right nasal cavity, so after intranasal administration, the major part of the administered 30 µl Evan’s Blue remained in the nasal cavity and the cannula can be used to administer compounds in the right nasal cavity in freely moving animals, with little or no drainage to other absorption sites.

When compared to other studies reported in literature, our experimental and handling techniques resulted in lower CORT concentrations, which indicates less stress during the experiments in freely moving animals. The intranasal administration did not increase CORT concentrations, and there were no differences in CORT concentrations when volumes up to 40 µl are administered, compared to IV administration.

With respect to the plasma and brain pharmacokinetics of acetaminophen we conclude that following IN administration no evidence was found for selective distribution enhancement to the brain. The administration of acetaminophen is site specific, as also concluded from the Evan’s Blue study. We do emphasize however that the administration of acetaminophen by the intranasal route shows a very rapid absorption indicated by identical PK when compared to IV administration.

In summary, the new intranasal administration method in freely moving animals allows the local, stress free administration of acetaminophen, while blood and brain pharmacokinetics can be observed over time.
