Violence has been observed in humans and animals alike, indicating its evolutionary/biological significance. However, violence in animals has often been confounded with functional forms of aggressive behavior. Currently, violence in animals is identified primarily as either a quantitative behavior (an escalated, pathological and abnormal form of aggression characterized primarily by short attack latencies, and prolonged and frequent harm-oriented conflict behaviors) or a qualitative one (characterized by attack bites aimed at vulnerable parts of the opponent’s body and context independent attacks regardless of the environment or the sex and type of the opponent). Identification of an operational definition for violence thus not only helps in understanding its potential differences from adaptive forms of aggression but also in the selection of appropriate animal models for both. We address this issue theoretically by drawing parallels from research on aggression and appeasement in humans and other animals. We also provide empirical evidences for violence in mice selected for high aggression by comparing our findings with other currently available potentially violent rodent models. The following violence-specific features namely (1) Display of low levels of pre-escalatory/ritualistic behaviors. (2) Immediate and escalated offense durations with low withdrawal rates despite the opponent’s submissive supine and crouching/defeat postures. (3) Context independent indiscriminate attacks aimed at familiar/unfamiliar females, anaesthetized males and opponents and in neutral environments. (4) Orientation of attack-bites toward vulnerable body parts of the opponent resulting in severe wounding. (5) Low prefrontal serotonin (5-HT) levels upon repeated aggression. (6) Low basal heart rates and hypo-responsive hypothalamus–pituitary–adrenocortical (HPA) axis were identified uniquely in the short attack latency (SAL) mice suggesting a qualitative difference between violence and adaptive aggression in animals.

Keywords: violence, aggression, animal models, mice, SAL

INTRODUCTION
Violence is a global concern, with severe implications for health, capital and the economy (in)directly (Krug et al., 2002). The World Health Organization (WHO) has defined violence as ‘the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of injury, death, psychological harm, mal-development or deprivation’ (Krug et al., 2002). Incidentally, violence is not restricted to human societies alone but has also been observed in a variety of other animal species, thus rendering animals a useful model for investigating violence. Research on violence in animals was first carried out in the last century using feral species, and has been commonly associated with crippling injury and/or death. This was originally investigated inter-specifically in predator–prey relationships (Southwick, 1970) but later was also observed under unusual environmental circumstances including captivity (Carpenter, 1934), crowding (Darling, 1937) or social disorganization of the population intra-specifically (Zuckerman, 1932; Carpenter, 1942; Calhoun, 1948; Southwick, 1955; Corbett, 1957; Carrington, 1958; Myers, 1966; Burns, 1968; Gilbert, 1968; Caras, 1969; Stokes, 1969). Violence has been documented from field studies in a number of vertebrate and invertebrate taxa, namely non-human primates, elephants, tigers, grizzly bears, lizards, social insects and rodents, suggesting a deep underlying evolutionary basis (Carpenter, 1934; Schaller, 1963; Lorenz, 1966; Southwick, 1970; Huntingford and Turner, 1987; Archer, 1988; Suomi, 2003; de Waal, 2005; Wrangham et al., 2006). Documentations of animal violence under (semi-)natural and controlled laboratory conditions have been carried out since then, primarily using different feline and rodent models. These studies have indicated additionally, a common biological underpinning for violence in humans and animals alike (described later).

Not withstanding the above, there has been a considerable awakening recently in the animal literature that violence may be confounded with naturally occurring, adaptive aggression. Here we provide several examples to clarify this controversy. We also propose a few key behavioral features that we believe would not only help in distinguishing violence from adaptive/functional aggression in animals, but also in offering ‘face’ validity to animal models of human violence. We describe several landmark manipulative studies on animals and address their strengths/weaknesses using our definitions. Further, the potentials and pitfalls of a particular mouse model, namely the SAL mouse, are assessed by comparison with other currently available rodent models and with human ‘violence’, using evidence from multiple disciplines.
VIOLENCE VERSUS AGGRESSION – OPERATIONAL DEFINITIONS

Animal violence has been studied through several manipulations (described later) using the following behavioral measures: attack latencies; frequency, intensity and duration of attack bouts; and frequency of attack bites. Violence in animals has been described as an escalated, pathological and abnormal form of aggression characterized primarily by early attack latencies, prolonged and frequent consummate behaviors and attack bites (Miczek et al., 2003). These parameters thus seem largely quantitative, in that violence is expected merely to show earlier attack latencies and higher frequencies and durations of consummatory behavior than adaptive aggression. Measures of a qualitative nature have been developed independently, where violence is considered qualitatively different from adaptive aggression. Attack bites, for instance, aimed at vulnerable parts of the opponent’s body are considered docile by nature (Haller et al., 2005). A few additional qualitative facets have been studied, namely lack of ritualistic behaviors as measured by Attack/Threat (A/T) ratios (Haller et al., 2005) and context independent attacks (Koolhaas, 1978) aimed at the opponent regardless of its sex or state (free-living/anaesthetized/dead) or the environment (home/neural cage). Violence can therefore in principle refer to an escalated (hyper-) aggression (quantitative) or to an abnormal form of aggression (qualitative), or even to aggression that is both escalated and abnormal (both), which is unsurprisingly rare (described later in this section). We provide a few evidences below to illustrate this ambiguity.

The first line of evidence for a possible difference between violence and aggression came from neurochemical studies in rodents. Van der Vegte et al. (2003) and de Boer et al. (2003) showed a positive correlation between 5-hydroxyindoleacetic acid (5-HIAA) levels and aggression in wild-type Groningen (WTG) rats, in contrast to human data where low 5-HIAA levels are associated with impulsivity and suicidal behaviors (Asberg et al., 1976; Brown et al., 1979). However, upon repeated/trained aggression, these highly aggressive rats showed a negative correlation between aggression and 5-HIAA levels, in line with the clinical data (de Boer and Koolhaas, 2005). The key difference is thus the shift in correlation from positive to negative, suggesting a possible experience-driven qualitative shift from adaptive aggression to violence. In line with the qualitative school of thought, de Boer et al. (2003) also showed absence of the highly aggressive phenotype in Wistar rats, a laboratory rodent model currently used for aggression research. These animals are considered docile by nature (Barnett and Smart, 1975; Ebert, 1976; Singleton and Hay, 1982). Although genetic information about laboratory rodent strains is abundant, use of docile strains lacking any appreciable aggression heavily questions their validity as models of human violence, in that the induced phenotype can be quantitatively more aggressive without necessarily being violent. This concern is heightened by the extensive use of these docile strains in several gene-knockout studies revealing possible single-gene effects on aggression and/or even violence (see Miczek et al., 2001 for review). Thus, the primary stumbling blocks in the understanding of violence have been the lack of operational definitions of violence and adaptive aggression in animals and the likely consequent use of inappropriate animal models.

In addition, in studies on humans, the term ‘violence’ is often used synonymously with ‘aggression’. Violence/aggression in humans has been identified primarily as a behavioral anomaly of social communication. However, studies on animals suggest that aggression and violence may be distinct phenomena (Haller and Kruk, 2006), which underlines the importance of clearly defining these terms, as we described above. Violence or maladaptive/pathological aggression in a simplistic sense has been defined as an exaggerated/escalated form of aggression leading to extreme harm in humans and animals alike. Aggression, on the other hand, has been defined primarily as a form of social communication, which is pro-inhibitory and aimed at functional endpoints such as the acquisition of food, shelter, mates and status (Scott, 1958; Koolhaas et al., 2010). Thus, there is inconsistency in the definition of these terms as applied to humans and animals.

This issue is highlighted by a brief survey of the scientific literature. A PubMed search with the keywords ‘violence, humans’ or ‘violence, animals’ or ‘aggression, humans’ or ‘aggression, animals’ yields a staggering 54,964 articles on ‘human violence’ since 1897 (491 articles per year on average), compared with only 1204 articles on ‘animal violence’ since 1968 (29 articles per year on average). There have been 21,925 articles on ‘human aggression’ since 1947 (353 articles per year on average) and 9691 on ‘animal aggression’ since 1962 (206 articles per year on average). A time-line of these publications from 1985 to 2007 is summarized in Figure 1. It is evident from the figure that the literature on violence in animals is sparse. In line with the above, violence has indeed been shown to be relatively rare in wild animal populations as well as amongst humans, which adds indirectly to the challenges (Mathews, 1964; Moffitt, 1993; Nagin and Tremblay, 1999; Suomi, 2003; WHO, 2004; Wrangham et al., 2006; de Boer et al., 2009). However, the publication discrepancy between human and animal violence could also stem from the lack of an appropriate definition for violence in animals. The terms ‘violence’ and ‘aggression’ are often used interchangeably across the human and animal literature without resolving what, if any, are the constructs or operational definitions unique to violence and adaptive aggression. Understanding the key differences between violence and adaptive aggression may thus help one to bridge the gap between the human and animal literature on violence (Haller et al., 2006).

BEHAVIORAL SEQUENCE LEADING TO AGGRESSION OR VIOLENCE

In our opinion, identifying valid animal models for pathological aggression first requires an appropriate operational definition for violence. The focal point of distinction between violence and adaptive (that is functional) aggression relies on the behavioral sequence or interaction dynamics between two or more conspecifics in combat. In other words, the sequence of agonistic behaviors between minimally an aggressor and its opponent that leads predictably to either adaptive aggression or violence is the key. Ideally, animal models for violence are not subjected to any inhibitory control, thus losing any adaptive function in social communication (Miczek et al., 2004; Haller and Kruk, 2006; Nelson and Trainor, 2007). Here, we outline the behavioral criteria we consider foremost in identifying intense/injurious aggression that may exceed normal species-typical levels and patterns. The following sections give a putative chronological sequence of behavioral components in the
agonistic actions often increase the apparent size of the animals concerned and/or expose their weapons. Agonistic encounters resolved without overt fighting are thus said to be 'ritualized'. Animals which possess the equipment for offense/defense exhibit aggressive behavior (Scott, 1958) but fighting amongst conspecifics is minimized by way of such ritualized behaviors, so that fights never end fatally and are generally no more than trials of strength followed by disengagement and rapid withdrawal by the weaker individual (Mathews, 1964). It is likely that violence bypasses the requirement for such ritualized behaviors, owing to altered motivations, which may be intentional or unintentional and are predominantly harm-oriented.

PRE-ESCALATION

Physical contact follows ritualization and often involves pushing, pulling or tail-beating contests, referred to as threat displays. These interactions involve the exploration/marking system (activated particularly by unfamiliar scents), as well as grooming (activated by secretions on the skin surface). In the wild, the opponents faced can be formidable and hence the deliberations during pre-escalation could be important even for a dominant animal. Such a rich behavioral repertoire potentially allows opponents to assess their relative strength, which may lead to the weaker one giving up before escalation takes place. This establishes dominance relationships amongst conspecifics (Huntingford and Turner, 1987). Submission in many group-living species inhibits aggression and gives rise to subsequent affiliative interactions (Preuschoft, 1995). Violence can thus be characterized by a marked lack of information about the opponent, which is followed by a (species-specific) reductionist
behavioral repertoire that lacks or displays inadequate threat behaviors and displays in general. Consummatory behaviors such as attack or escalated aggression may supersede ritualistic threat behaviors in violent individuals.

ESCALATION
In animal aggression, ritualization and pre-escalation are followed by a stage marked by energetic and potentially dangerous actions (such as biting, kicking and striking). This progressive increase in the intensity of the conflict is described as escalation (Huntingford and Turner, 1987). Conflicts can be resolved by one participant retreating at any point in the escalation sequence, so that full-scale physical attack is not a necessary component of all animal fights. These conflicts are often short, rapid and aimed at delivering the status of dominance and the ability to acquiring resources in the group. Violence, however, may entail pronounced esculatory behavior, characterized by longer or more frequent consummatory actions or both, targeting an opponent and its vulnerable body parts regardless of its subordination or submissive status.

An all-out tooth and claw fight may occur in exceptional circumstances, for example when resources (food/mates/space) are limited, or when competitors have the same levels of motivation, or when they are willing to risk their ability or status (as expected in the declining phase of a population), or when they have imperfect information about their power asymmetry (Smith and Parker, 1976). Such conflicts may have consequences for the regulation of population size, by compromising the reproductive success of subordinates or affecting mortality, emigration and/or the re-establishment of dominance hierarchies (van Oortmerssen and Busser, 1987). Experimental instances of violence in the lab are thus expected to be relatively rare when the animals are provided with food (ad libitum), partners and territory and therefore face no substantial environmental challenges.

POST-ESCALATION
Given the long-lasting negative consequences of conflicts in general, the post-escalation phase is integral in individuals of many group-living species regardless of their familiarity. Establishment of stable hierarchical societies or family groups is feasible only due to post-conflict affiliative behaviors (Preuschoft and van Schaik, 2000). Conflict resolution often occurs through affiliative contacts like gentle touching, as seen in humans, rhesus monkeys and horses (Drescher et al., 1980, 1982; Feh and de Mazieres, 1993), and allo-grooming, as seen in monkeys (Boccia et al., 1989; Aureli et al., 1999). Violence typically lacks any post-conflict appeasement behaviors. Submission by a weaker opponent may not be pro-inhibitory, but in fact may provoke further violence. In other words, withdrawal behaviors might be disproportionately lower to the observed consummatory behaviors in a violent conflict.

CONTEXT DEPENDENCY
Agonistic interactions are often modulated by the environment (e.g., known/unknown territory; home/neutral environments) and by the opponent’s status, sex (e.g., male–male agonistic encounters are more common than inter-sexual conflicts) and familiarity. Escalated fighting is less frequent among familiar individuals than strangers (Karavanich and Atema, 1998), allowing the former to save the time and risks associated with assessment and escalation. These benefits may help to stabilize associations among many group-living or territorial animals, including those that are submissive (Preuschoft, 1995). Context-independent attacks are often seen in mammals in that they aim human habitats when their own habitats are threatened (Corbett, 1957). Violent human offenders are also known to attack and indulge in unacceptable norms and practices including sexual/vocal/physical abuses that are inappropriate and context-independent (Agnew, 1998). Violence may be context-independent, i.e., incapable of discriminating between opponents or environmental contexts.

In summary, adaptive aggression seems to be a functional, dynamic, flexible yet structured behavior within certain limits, achieved by a pattern of constrained actions, reactions and social signals between the opponents in conflict. As such, it appears to involve strong inhibition against causing harm, unless strictly necessary. Violence, on the other hand, seems highly disinhibited and indiscriminate to a conspecific. Violence can therefore be considered an aggressive behavior that is out of control (uninhibited), out of content (pattern and structure of the agonistic combat) and out of context, making it qualitatively different from other forms of aggression. Inclusion of these criteria in aggression models will add to their validity, thereby expanding our knowledge of the underlying neurobiological correlates of pathological and violent forms of human aggression.

ANIMAL MODELS OF VIOLENCE
Now that we have defined violence and adaptive aggression, we move on to consider some of the more important animal models in detail and describe how they have contributed to our understanding of violence. Replication of feral violence (as described in the introduction) in the lab has been a multidisciplinary effort, in that much of the information about violence and aggression has come from manipulative studies at neurophysiological, environmental, neuropharmacological and genetic levels. We describe some of these studies below.

NEUROPHYSIOLOGICAL MANIPULATIONS
Neurophysiological manipulations, involving electrical stimulations and lesions of the brain, were the preliminary experimental methodologies for studying the brain mechanisms of aggression in the early 19th century. Several methodological techniques were used, from gross regional ablations (e.g., decerebration) to focal lesions and electric stimulations of several brain regions in cats, monkeys, dogs and rats. Siegel (2004) provides an excellent review of these approaches. In particular, identification of classic defensive rage responses and predatory attack behavior models in cats contributed significantly to the understanding of the neural control of aggressive attack in the last century. The rage response has been shown to share physiological (sympathetic arousal, e.g., increase in heart rate and blood pressure) and behavioral (repertoire limited in time or to events of short duration; ritualized behavioral postures prior to the consummation act) features with the impulsive or unplanned human violence seen in intermittent explosive disorder (Meloy, 1988). The predatory attack model seems to overlap with human psychopathy in that it was not symptomatically mediated, positively reinforcing to the self and hence compulsive,
planned with precise and intense delivery to the victim, and with no apparent threat in the vicinity (Meloy, 1988). The human counterpart also involves focusing on the target by filtering out sensory information, in much the same way as a cat does when focusing on its prey (Meloy, 1988).

Electric stimulation of specific brain regions were also carried out subsequently in rats, triggering biting attacks on the neck, head or back (Woodworth, 1971; Koolhaas, 1978) coupled with paw kicks to the flank, clinch fights and attack jumps (Kruk et al., 1979; van der Poel et al., 1982; Lammers et al., 1988). The electrical brain-stimulated (hypothalamic activated attack, HAA) rat model of aggression and the glucocorticoid-deficient rat model (described later on) has also helped in identifying additional behavioral parameters that include differential contexts, such as the resident’s response to the opponent’s status (dominant/subordinate; anaesthetized/dead) and sex (male/female).

Thus, neurophysiological studies in cats and rodents laid the foundations for the analysis of offensive and defensive components of violence and aggression with some clinical validity to human violence. These neurophysiological manipulations additionally also paved the way to the discovery of several neuromodulatory substrates of violence and aggression in the brain, amongst which the prefrontal cortex, hypothalamus and periaqueductal gray (PAG) deserve special attention.

**Neural substrates of violence/aggression**

The prefrontal cortex has been identified as a primary inhibitory center of aggression and violence in both humans and animals. The earliest reports on its role as a modulator came from Gage's accidental prefrontal lobotomy leading to uninhibited child-like behavior in the intellectual abilities and passions of a strong man (Harlow, 1848, 1868). Stimulation of medial/lateral (orbital) prefrontal cortex for instance, caused profound suppression of predatory attack and defensive rage by increasing the latencies to attack (Siegel et al., 1974, 1975). In rats, bilateral thermal lesions in the ventrolateral prefrontal cortex increase the duration of lateral threats (de Bruin et al., 1983; de Bruin, 1990). Recently, PET studies have confirmed the prevalence of prefrontal cortex malfunctioning in highly aggressive people (Enserink, 2000; Raine et al., 2000; Lee and Coccaro, 2001).

The classic rage response described earlier has been shown to be elicited by electric activation of the medial hypothalamus, ventral tegmentum, stria terminalis, and PAG in the cat (Siegel, 2004). Predatory attack behavior or quiet attack (Wasman and Flynn, 1962) can be elicited by electric stimulation of the lateral hypothalamus/midbrain. This has also been shown in rats that have been electrically stimulated in the hypothalamus (Koolhaas, 1978; Kruk et al., 1979; Kruk, 1991; Haller et al., 2001; Halasz et al., 2002). Several neurological disorders in humans implicate the involvement of hypothalamus, PAG and other limbic structures in the control of aggression and rage (Siegel and Victoroff, 2009). These include temporal lobe epilepsy, sclerosis of the temporal lobe, and tumors of the temporal lobe, hypothalamus and other limbic structures. At a pre-clinical level, defensive rage in cats has been proposed to be mediated by a glutamatergic neurotransmitter pathway from the amygdala and hypothalamus to the PAG, which in turn leads to an exaggerated response to stimulation (Siegel et al., 1999; Yao et al., 1999). However, these models require further behavioral validation to ascertain the pathological nature of aggression.

**ENVIRONMENTAL MANIPULATIONS**

Early lab studies in rodents were primarily non-physiological, non-ecological manipulations including social isolation, electric-shock-induced attack, and tube restraint attack (Brain, 1989). Later, manipulations used ecologically more relevant human contexts including repeated winning or losing experiences (Andrade et al., 1989) and several other aggression-inducing or stressful conditions such as frustration, social instigation and mild uncontrollable stress. Stressful experiences, especially in early life, have been strongly associated with violence and anti-social behaviors in humans (Deater-Deckard and Plomin, 1999; Kendler et al., 2003) and macaques (described under Section 'Genetic Manipulations'). Since the 1970s, extensive environmental manipulations have been carried out to induce or enhance aggressive behavior, particularly in rodents. These are described below.

**Aggression induced by social isolation**

Abnormal behaviors seen in adolescents and adults are considered to be causally related to disruption of early attachment (Bowlby, 1969, 1988; Ainsworth et al., 1978; Kraemer, 1992), a theory supported by studies in rhesus monkeys (Harlow et al., 1971). Similarly, seclusion in prison inmates and asylum patients is associated with pathological behaviors (Farrell and Dares, 1996). Social isolation was one of the earliest and most frequently used methodological approaches to induce or enhance fighting in animals as well (Brain, 1989). Male rodents were isolated for 2–8 weeks or even longer, and subsequently confronted with a house-mated caged specific in an unfamiliar test arena or in the isolate’s home cage (Vekovischeva et al., 2007). Isolated subjects were found to display enhanced and prolonged aggression (Brain, 1989). Expression of inappropriate adult aggressiveness is also observed in a wide variety of animal species after maternal separation or early-life social isolation (Veenema, 2009).

**Aggression induced by provocation**

Prior exposure to a myriad of acute or chronically applied stressful stimuli is known to induce aggression in humans (Craig, 2007; Herrenkohl et al., 2007), as well as in experimental animals when tested during a subsequent resident-intruder interaction (Haller et al., 2004). Acute provocation strategies have been used in rodents, for example by applying intensely noxious and/or painful stimuli like electric shocks just before or during a brief social confrontation (Brain, 1989). More recently, the exposure of mice to an unpredictable chronic mild stress protocol for several weeks was reported to enhance levels of aggression (Mineur et al., 2003).

**Frustrative non-reward** represents a procedure with exceptional effectiveness in provoking very high levels of aggressive behavior in fish, birds, rodents, pigs, monkeys and humans (Dollard et al., 1939; Azrin et al., 1966; Thompson and Bloom, 1966; Cherek and Pickens, 1970; Arnone and Dantzer, 1980; Miczek et al., 2002, 2003; Leary et al., 2006). Organizational and management research has focused on (mal)adaptive work behaviors and implicates organizational aggression as a counter-response to frustration (Fox and
Aggression was also acutely increased in cross-rearing events. This was demonstrated in mice and has been shown to be associated with high rates of criminality, alcohol dependence and premature death due to murder. Reduced blood platelet 5-HT binding or blood tryptophan levels have also been linked with a history of violent behavior.

The sudden and unpredictable omission of reinforcement just before confrontation with an opponent enhances aggressive behavior in animals. One of the first studies was carried out by Pavlov (1927), who conditioned dogs to associate the arrival/withholding of food with a specific geometrical shape. However, when the different shapes presented were manipulated to look alike, the subject became confused and eventually aggressive, apparently out of frustration. A resident animal can also be provoked by placing an instigator or opponent into its home cage behind a protective screen for a short time prior to the actual physical confrontation. This is known to accelerate and/or enhance aggressive attacks. This so-called social instigation/provocation or priming procedure has been successfully demonstrated in mice (Fish et al., 1999), rats (Potegal, 1992) and hamsters (Potegal et al., 1993).

Aggression heightened by anticipation or experience

This procedure is based on the induction and learning of aggressive behavior upon repeated stimuli that can reinforce operant responding in humans and other animals (Thompson, 1964; Connor, 1974; Potegal and Eimon, 1989; McSweeney and Swindell, 2002). Berkowitz (1984, 1989, 1993) has proposed a ‘cognitive neoassociation model of aggression’ in which, when people are repeatedly exposed to aggressive situations (for instance, video games, Dill and Dill, 1998), detailed and inter-connected aggressive thought networks are created. These authors propose that playing violent video games leads to the learning of violent behaviors as an acceptable way of solving problems and may desensitize the participants to violence.

Similarly, animals are motivated to perform an operant (nose-poke or lever-press response) where the opportunity to get access to an opponent and display aggressive behavior serves as the reinforcer (Miczek et al., 2002). This indicates that, even though aggressive confrontations may be extremely stressful or anxiogenic, the performance of aggression can function as a potent positive reinforcing event (Miczek et al., 2002, 2004; Coupps and Kennedy, 2008). Providing an animal with repeated positive (i.e., winning) aggressive experiences in its home cage generally leads to an increase in aggressiveness (Kudryatseva, 2000; Kudryatseva et al., 2000). After extended repeated winning experiences, certain individuals may start to attack with very short latency, high intensity and high frequency and without regard to signals of submission, often leading to severe wounding of the opponent (Hsu et al., 2006).

NEUROPHARMACOLOGICAL MANIPULATIONS

Scientists began to identify the neurochemical substrates behind violence since the 1960’s. Low concentrations of the brain neurotransmitter serotonin (5-HT) were linked with high aggression in mice, 5-HT turnover to the metabolite 5-HIAA (as indicated by low levels in the cerebrospinal fluid) were linked to violence in humans (Maas, 1962; Garattini et al., 1967; Asberg et al., 1976; Brown et al., 1979; Linnoila and Virukken, 1992). In particular, low 5-HIAA levels have been found to predict explosive aggression and impulsive violence in conduct-disordered boys and have been associated with social incompetence (Siever and Trestman, 1993). This neurochemical condition has also been reported in arsonists and has been shown to be associated with high rates of criminality, alcohol dependence and premature death due to murder (Lewis, 1991; Berman and Coccaro, 1998). Primates, including the rhesus macaques mentioned earlier, have also been shown to display anti-social behavior patterns with deleterious impulse-control deficits of demonstrable trait-like stability throughout life, associated with low 5-HIAA levels (Higley et al., 1991). Other behaviors found to be associated with low 5-HIAA levels include unrestrained aggression, impulsive risk-taking, excessive alcohol intake and most severe forms of violence leading to trauma and early death. More recently, several pharmacological manipulations have been used, both centrally and peripherally, to study various neurotransmitter systems including 5-HT and other related neurochemical circuitries. A few selected studies are described below.

Aggression induced by serotonin depletion

Many studies have sought to identify a causal relationship between low 5-HT levels and aggression, using a variety of manipulations including dietary restriction of the 5-HT precursor amino acid tryptophan, inhibition of 5-HT synthesis by administration of the tryptophan hydroxylase (TPH) inhibitor p-chlorophenylalanine (PCPA), and destruction of serotonergic neurons by administration of the serotonin neurotoxin 5,7-dihydroxytryptamine (5,7-DHT). Chronic tryptophan depletion in rats increased shock-induced aggression (Kantak et al., 1980a,b) and muricidal behavior (Gibbons et al., 1978). Aggression was also acutely increased in human male subjects, particularly those with high trait aggression, when they were administered tryptophan-free amino-acid mixture (Chamberlain et al., 1987; Cleare and Bond, 1995; Pihl et al., 1995; Bjork et al., 2000; McClosey et al., 2009). This was also observed in rodents (Bell et al., 2001). Rats in which serotonin neurons were lesioned with 5,7-DHT, showed more shock-elicited aggression and muricidal behavior (Breese and Cooper, 1975; Hole et al., 1977; Kantak, 1981; Kantak et al., 1981; Vergnes et al., 1988). An increase in muricide and offensive aggression was also observed when rodents were injected with PCPA (Miczek et al., 1975; Paxinos et al., 1977; Gibbons et al., 1978; Valzelli et al., 1981; Sewell et al., 1982; Albert et al., 1985; Ieni and Thurmond, 1985; Molla-Hosseini, 1985; Vergnes et al., 1988; Keele, 2001).

Aggression heightened by alcohol

Alcohol ingestion has also been shown to induce aggressive behavior in humans. In the United States between 1993 and 1998, 30–40% of crimes committed involved an offender who had consumed alcohol prior to the crime (Greenfield and Henneberg, 2000). Cross-cultural studies have shown a greater-than-chance involvement of alcohol in homicide and violent crime (Murdoch et al., 1990). A meta-analysis of experimental research on alcohol and aggression suggests a general increase in aggression after consuming alcohol, especially for men (Bushman and Cooper, 1990; Bushman, 1997). Not only is alcohol associated with an increase in aggressive...
behavior, there is also some evidence to suggest that the effects of alcohol consumption may contribute to the escalation of conflict and increased risk of injury when aggression does occur (Martin and Bachman, 1997; Sharps et al., 2001; Brecklin and Ullman, 2002). Alcohol-heightened aggression (AHA) has been modeled in alcohol-treated rodents, which show frequent attack bites compared to controls (Fish et al., 1999; Miczek et al., 2004).

**Aggression induced by low glucocorticoids**

Glucocorticoid hypofunction has also been associated with abnormal aggression and violence. Habitually violent offenders with anti-social personalities show lower levels of plasma glucocorticoids than healthy subjects and non-habitual violent offenders (Virkkunen, 1985). It has also been shown that plasma glucocorticoid levels are inversely associated with aggressiveness in children with conduct disorder (McBurnett et al., 2000). Low basal levels and hyporesponsiveness of plasma glucocorticoids are associated with persistent aggression in humans (Pajer et al., 2001; Kariyawasam et al., 2002) and this finding has also been documented in dogs and rainbow trout (Hennessy et al., 2001; Pottinger and Carrick, 2001). Haller et al. (2001) generated adrenalectomized (ADX) rats supplemented with subcutaneous glucocorticoid pellets to ensure a low and constant level of glucocorticoids in the plasma. These rats showed several of the salient features described in the sections earlier, including attacks aimed at vulnerable parts of the intruder’s body, high A/T ratios and poor social exploration, supportive of a qualitative difference between violence and adaptive aggression.

From the above manipulations (environmental/pharmacological), one can infer that many factors promoting aggression in humans (psychological, alcohol-induced, low glucocorticoid levels) have similar effects in animals, which is suggestive of shared underlying biological mechanisms.

**GENETIC MANIPULATIONS**

Acute (emotional) stress and social subordination has been shown to induce an interplay of ‘gene’ × ‘environment’ interaction in heightening aggression, primarily via the 5-HT system. This is translated as a downregulation of the activity and expression of specific 5-HT components, namely monoamine oxidase A and B (MAO A, B) and serotonin transporter (SERT). Brunner et al. (1993) showed the segregation of a complex behavioral syndrome (including impulsive aggression and dysfunctional sexual attitude) with a nonsense mutation resulting in null activity of the enzyme MAO A in males from a Dutch pedigree. Possession of a low-activity allele of the MAO genotype was associated with anti-social behavior upon maltreatment (Casi et al., 2002). Maladaptive social behaviors, such as those seen in schizophrenia, suicidal depression, cluster-B personality disorders and attention deficit/ hyperactivity disorder (ADHD), are associated with impulsivity and with the SERT gene-linked polymorphic region (5-HTTLPR allele) – the short/short (SS), short/long (SL) genotypes, and are only exacerbated by environmental adversities and individual life-history experiences (Retz and Rosler, 2009). Recently a ‘bottom-up’ molecular genetic approach (i.e., single-gene knock-out and transgenic over-expression) was used to assess the polygenic nature of aggression and violence. This approach has so far identified at least 75 genes as playing a role, including the nitric oxide synthase (NOS-I) gene (Reif et al., 2009), Dopamine receptors D2 gene variants and Dopamine transporter (Guo et al., 2007). For detailed reviews, see Miczek et al. (2001), Nelson and Chiavegatto (2001), and Retz and Rosler (2009).

The earliest evidence regarding the genetic basis for violence came from heritability studies (Blonigen and Krueger, 2006). Breeders selected either for docility or for a strong tendency to attack, as seen for example with dogs and chickens. These informal observations and a few systematic studies of the patterns of inheritance for violence and aggression carried out earlier (Yerkes, 1913; Utsurikawa, 1917; Coburn, 1922) indicate that this complex behavioral trait is influenced genetically. The alternative, classic ‘top-down approach’ genetic approach focused on selective breeding for aggression in rodents, as in the Turku Aggressive (TA) and Turku Non-Aggressive (TNA) mice (Lagerspetz, 1961), SAL and long attack latency (LAL) mice (van Oortmerssen and Bakker, 1981), and the North Carolina Aggressive (NC900) and North Carolina Non-Aggressive (NC100) mice (Sandnabba, 1986). Box 1 offers a detailed description of the selection of these mice. In particular, the SAL mice, selectively bred from a wild population from Groningen, the Netherlands, have been strongly associated with violence over the years (discussed below in Section ‘SAL Mice as an Animal model for Violence’).

Despite the availability of several approaches and manipulations in animals (as described above), most of these studies have failed to tackle the controversial issue of defining violence and its delineation from adaptive aggression. Their focus has primarily been on documenting the different types of violence or aggression displayed. For instance, as mentioned earlier, feline models have revealed different forms of violence, namely predatory attack or instrumental violence and defensive rage or affective aggression. Rodent models focus on specific physiological aspects of violence (basal heart rate and glucocorticoid response to stress) leading to the identification of hypo- and hyper-arousal-driven forms of aggression. Several studies define offensive and defensive forms of aggression but none of these models helps to elucidate the possible distinction between violence and aggression. Several of the pharmacological models aimed at 5-HT depletion have often proved contradictory, in that the aggression outcomes were inconsistent. For a few other models of induced aggression (e.g., frustration, social instigation and other pharmacological manipulations aimed at 5-HT and other neurotransmitters), it is highly questionable whether this induced aggression is pathological or not. Thus, there is a pressing need to identify those animal manipulations that offer face (symptomatological), construct (etiological and neurobiological) and predictive (pharmacological) validities to human violence. de Boer et al. (2009) have argued that most of the manipulations described above lack face validity, owing to controversies regarding the operational definition of violence and its distinction from other forms of animal aggression.

**SAL MICE AS AN ANIMAL MODEL FOR VIOLENCE**

Differences between violence and adaptive aggression were recently established using SAL, TA and NC900 mice, genetically selected for high aggression (see Box 1 for details). The males from these mouse lines were compared for their agonistic behaviors when subjected to a resident-intruder paradigm based primarily on social
Behavioral latencies (relevant to the resident-intruder behavioral exchanges) was used owing to their high occurrences in the highly aggressive mice. Similar studies have been carried out in characterizing alcohol-induced heightened aggression in rats (Miczek et al., 1992). Behavioral testing has been described in detail elsewhere (Caramaschi et al., 2008a; Natarajan et al., 2009a).

**SAL is qualitatively different from TA and NC900 mice**

Several behavioral features of SAL, TA and NC900 mouse lines were derived with reference to the criteria described in section ‘Behavioral Sequence Leading to Aggression or Violence. Most of our understanding of violence and its delineation from aggression has stemmed from male–male interaction studies carried out in these mice.

**Intent**

All the high-aggressive mouse lines displayed consistently low latencies of attack, while the low-aggressive lines displayed high attack latencies (Caramaschi et al., 2008a; Natarajan et al., 2009a). In particular, the SAL mice had the lowest attack latencies right from day 1 when compared to the TA or NC900 mice lines. However, repeated winning experiences lowered the attack latencies in TA and NC900 mice subsequently (Caramaschi et al., 2008a).

**Ritualization and pre-escalation**

Using behavioral kinetograms, Natarajan et al. (2009a) showed that the SAL mice investigate their opponents less than TA, NC900 or the low-aggressive mouse lines (Figure 2). Earlier, Halasz et al. (2002) reported heightened A/T ratios in the ADXR rats (2002), suggestive of immediate consummatory action without appropriate ritualistic/pre-escalatory behaviors. High A/T ratios were also shown in SAL mice (Caramaschi et al., 2008a). Natarajan et al. (2009a) modified A/T ratios to incorporate ‘chase’ behaviors as part of the consummatory process as the threat/attack + chase) [T/(A+C)] ratio. Low T/(A+C) ratios were observed in SAL mice, suggesting a similar lack of ritualistic/pre-escalatory behaviors (Natarajan et al., 2009a). Despite showing lower attack latencies, TA and NC900 mice still displayed ritualistic and pre-escalatory behaviors and were inhibited by the opponent's submissive behavior, as shown by a higher magnitude of their own transitions to non-social exploratory behaviors (Figure 2, right half).

**Escalation**

The measures of offense used for all three high-aggressive mouse lines were duration and frequency of attack, chase and threat behaviors. Interestingly, the lines did not differ significantly for any of these behaviors. This confirms the idea that offense is a measure of...
SAL mice failed to respond to the inhibitors’ submissive behavior, as seen by the locked-in attack-chase offensive interplay when compared to TA and NC900 mice. SAL mice also showed more attack-chase behavioral transitions than NC900 (refer Figures 2A,B) and the least withdrawal behavior, and hence showed a high ratio of withdrawal to offense rates (O/W, Natarajan et al., 2009a). Earlier, Haller et al. (2006) showed that a third of SAL attacks targeted the vulnerable parts of the opponent’s body, compared to the low-aggressive counterpart LAL, pointing to the potentially lethal nature of SAL mice (Natarajan et al., 2009a).

The SAL mice were, however, shown to possess a stable and diverse display of extremely offensive behavioral transitions across three successive days of agonistic combat, in comparison to the moderate and stable NC900 line and the declining TA line (Natarajan et al., 2009b). An increased frequency and duration of offensive behaviors was also salient in rodents that showed AHA and those that were modeled for social instigation, frustration as well as in those that were administered midozolam (Miczek et al., 2003, 2004; Fish et al., 2005).
of their attack strategies. This is similar to the HAA rats (Kruk et al., 1990) and ADxR rats, which attacked the head of the opponent. The latter were also shown to preferentially attack vulnerable parts (head, throat and belly) of their opponents, up to 70% of the total number of attacks. Such attacks were rare in control rats (only between 3–10%, Haller et al., 2004).

Post-escalation
Although none of these high-aggressive mouse lines were shown to groom their male opponent after a conflict, it was evident that TA and NC900 lines resorted to innocuous cage exploration after a brief period of escalated behaviors (Figure 2, right half). The SAL mice showed more transitions from offensive behaviors to immobility, which is suggestive of physical exhaustion (Figure 2, left half) rather than sensitivity to the attacked opponents (Natarajan et al., 2009a). Unlike SAL, TA and NC900 interactions with the intruder were further characterized by a rich repertoire of submissive and moving-away behaviors (Caramaschi et al., 2008a; Figure 2, bottom panel).

Context-dependency
The SAL mice failed to discriminate between anaesthetized mice, free-moving mice, and female partners regardless of their familiarity or estrous status (Caramaschi et al., 2008a; Natarajan et al., 2009a), as has also been observed in HAA (Kruk et al., 1990) and ADxR rats (Haller et al., 2004). The partner offense behavior in particular has been observed to worsen with age in SAL mice, but not in TA and NC900 mice (personal observations).

In summary, the aggressive behavior displayed by SAL mice is in line with the definitions of violence put forth in Section ‘Behavioral Sequence Leading to Aggression or Violence’. The above findings are also suggestive of a ‘qualitative’ behavioral difference between violence and adaptive aggression. de Boer et al. (2009) found a similar pattern in the WTG rats, characterized by early attack frequency, long and frequent consummatory behaviors, and indiscriminate attacks on female conspecific partners and anesthetized male intruders. WTG rats were also shown to focus their attacks primarily on the vulnerable parts of the opponent’s body, as with the SAL mice and the ADxR rats. It is also apparent that conventional comparison of the behavior of the SAL mice with the LAL mice (their low- or non-aggressive counterpart) failed to reveal the violent dispositions of the former. Thus, the identification of violence is most appropriate when the test animal shows appreciable levels of aggression. The high-aggressive mice were shown to display a 15–40% aggression levels by both duration and frequency (Natarajan et al., 2009a).

5-HT Neurochemistry
Brain 5-HT levels were assessed in these mice both when naïve and after repeated agonistic interactions. Under naïve, non-fighting conditions, low 5-HT levels were not a consistent feature of the high-aggressive lines (Caramaschi et al., 2008a; Natarajan et al., 2009c). After repeated agonistic encounters, however, the tissue levels of forebrain 5-HT and its metabolite were generally lower in the high-aggressive lines than in the non-aggressive lines (Lagerspetz et al., 1968; Olivier et al., 1990; Veenema et al., 2005). The lowest prefrontal cortical 5-HT levels were characteristic of SAL mice when their aggression levels were saturated to the highest limit (Caramaschi et al., 2008a). This finding is in line with the human data on violence as well as with the 5-HT data from the WTG rats (Section ‘Animal Models of Violence’).

However, the expected lowered 5-HIAA levels and 5-HT turnover (due to repeated agonistic interactions) were not restricted to SAL mice alone. Similar declines were also observed in the other mouse lines, regardless of their aggressive tendencies (Caramaschi et al., 2008a). This difference from the human data can be attributed to three possible reasons. First, regulation of intra/extracellular 5-HT levels is not straightforward and is often seen as an interplay between several mediating proteins and enzymes, including TPH (enzyme that synthesizes 5-HT), MAO (enzyme that degrades 5-HT), 5-HT receptors, SERT (5-HTT, transporter protein that helps in sequestering 5-HT in vesicles) and vesicular-matrix-associated transporter (VMAT, transporter protein that helps in sequestering 5-HT in vesicles within the 5-HT neurons). It is possible that one or more of these players are differentially regulated, which might mask the otherwise violence-related hypo-serotonergic condition. The functional activities of these serotonergic candidates have just begun to be assessed for their likely role as neurochemical correlates of violence in the SAL mice (e.g., 5-HTT<sub>1A</sub>, 5-HTT, TPH, MAO). An enhanced sensitivity of the 5-HT<sub>1A</sub> autoreceptor seems to be one of the plausible causative mechanisms of maladaptive aggression (Caramaschi et al., 2007). The low serotonin levels in SAL mice are associated with enhanced sensitivity of the presynaptic and postsynaptic 5-HT<sub>1A</sub> receptor and its expression in cortico-limbic structures (Korte et al., 1996; van der Vegt et al., 2001; Feldker et al., 2003; Veenema et al., 2005; Caramaschi et al., 2007). The enhanced 5-HT<sub>1A</sub> receptor functionality may result in inhibited tonic release of 5-HT. The consequence is probably an impaired serotonergic neuromodulation in key areas of behavioral inhibition control, such as the prefrontal cortex, leading to impulsivity. Secondly, CSF 5-HIAA levels, measured in humans and other primates, indicate the leftovers in the extracellular compartments, and are not directly comparable to the 5-HIAA levels or 5-HT turnover in the intracellular compartment of cortical neurons measured in mice and rats; thus posing a methodological challenge. Finally, certain environment/experience effects can also contribute to specifically lowering 5-HIAA levels (as seen in violent humans). This needs to be modeled in the SAL mice.

Functional neuroanatomy
The neural activation patterns of SAL mice associated with their exaggerated aggressive behavior have been scrutinized by Haller et al. (2001) using c-Fos immunocytochemistry. Agonistic encounters in
the SAL mice were found to strongly activate the following brain regions: medial prefrontal cortex (infralimbic and prelimbic subdivisions), central amygdala, lateral/ventrolateral PAG, lateral septum, bed nucleus of stria terminalis and locus ceruleus.

Central amygdala activation was also observed in rats that were electrically stimulated at the HAA as well as in ADxR rats (Haller et al., 2006). Adrenalectomized rats showed an additional activation of the paraventricular nucleus of the hypothalamus (involved in the control of the HPA axis) when compared to controls (Haller et al., 2003). Activation of the lateral/ventrolateral PAG and bed nucleus of stria terminalis has been observed during predatory aggression in cats. Predatory attack behavior or quiet attack (Wasman and Flynn, 1962), elicited by electric stimulation of the lateral hypothalamus/midbrain, led to strong bites typically at the back of the victim's neck (Wasman and Flynn, 1962; Flynn, 1976). The cat was often seen to lunge at the rat, striking it and placing a paw on it to position the victim, as well as positioning itself to bite the rat. The cat's pupils were usually dilated and moderate piloerection was observed. Vocalization and initial stalking of the prey were absent. As described earlier, predatory attack behavior in animals seems to overlap with human psychopathy where it is not sympathetically mediated (Meloy, 1988).

In addition to these brain areas, the medial amygdala was also activated in the SAL mice, which is the case during affective aggression in cats. Classic rage response/defensive rage behavior was elicited due to activation of the medial hypothalamus, ventral tegmentum, stria terminalis, and PAG in the cat (Siegel, 2004). The associated changes include sympathetic responses, namely an increase in heart rate and blood pressure, and behavioral responses such as hissing, retraction of the lips, laying back of the ears, arching of the back and marked piloerection (Magoun et al., 1937; Ranson and Magoun, 1939; Hess and Akert, 1955; Hunsperger, 1956, 1959, 1969; Layhausen, 1979).

The SAL mice thus seem to show neurobiological activation typical of both reactive and predatory/instrumental aggression, as seen in anti-socially disordered patients (Haller et al., 2005). Brain areas typical of territorial aggression, such as the dorsolateral PAG and lateral septum, were not activated in the SAL mice, suggesting a lack of territorial aggression in this model. Further investigations are required to resolve the neurobiological correlates in SAL mice pertinent to either instrumental or reactive violence. Comparative studies with TA and NC900 mouse models might offer this possibility.

**Stress physiology**

From an endocrine/physiological perspective, violence has been identified predominantly as either the reactive, hostile, emotional aggression or the instrumental or cold-blooded aggression as described in Section ‘Animal Models of Violence’. While the former is consequential upon high stress reactivity in the sympathetic-adrenomedullary system and/or in the HPA axis (anger and high emotional response), the latter is observed without any emotional arousal.

In line with the above findings, Caramaschi et al. (2008b) have shown a low resting heart rate in the SAL mice compared to TA or NC900, suggesting an imbalance in sympathetic/parasympathetic cardiovascular regulation shifted toward the low sympathetic or high parasympathetic (or both). In addition, the SAL mice showed a hyporesponsive HPA axis in comparison with the LAL mice (Veenema et al., 2003a). The response of the main rodent glucocorticoid hormone, corticosterone, to ACTH was significantly lower in SAL than in LAL mice. Chronic psychosocial stress induced long-lasting corticosterone increase in LAL mice compared to SAL mice. The dark-phase-related rise in corticosterone was also found to be less marked in SAL than in LAL mice (Veenema et al., 2003b). A similar observation was made with the ADxR rats, which increased their corticosterone levels by less than a half when under social stress. These rats were thus shown to display autonomic hypoarousal in addition to attacking the vulnerable parts of the opponent's body, as described earlier. They also showed social deficits in the social interaction test, similar to SAL mice (Figure 2, left half). This observation did not appear to result from a general increase in anxiety, as the rats failed to show signs of anxiety in other tests (elevated plus-maze and light/dark tests, Haller et al., 2005). Thus, the SAL mice can be considered to be stress hypo-reactive, like the ADxR rats with respect to heart rate and glucocorticoid production (Haller et al., 2001; Veenema et al., 2003a,b).

**DOES ANIMAL VIOLENCE TRANSLATE TO HUMAN VIOLENCE?**

In the previous section, we attempted to delineate violence from adaptive aggression in mice and assess its significance in various rodent models that are currently available. As a logical follow-up, one would like to confirm the validity of SAL violence as a model of human violence. Sluyter et al. (2003) envisaged SAL mice as a potentially valid model of human anti-social behavior, based on a number of measures including predisposition to alcohol, litter size and personality. A comparison of these rodent models is presented in relation to human violence in Table 1. Considering the behavioral criteria of violence outlined in Section ‘Behavioral Sequence Leading to Aggression or Violence’, we may conclude that the SAL model has a considerable degree of face validity to human violence. For instance, a lack of sensory processing (as described in Section ‘ViolenceVersusAggression—OperationalDefinitions’underprecursatorialbehaviors)hasbeenattributedtoa deficiency in processing negative stimuli (specifically sad or fearful facial expressions or vocals) in human subjects with psychopathy and its dispositions (Somer et al., 2006). Individuals who frequently engage in anti-social behavior using instrumental aggression have been shown to display a reduced sympathetic baseline tone and low HPA axis tone and activation (Virkkunen, 1985; Raine et al., 1990, 2000; Scarpa and Raine, 1997; Raine, 2002a,b; Popma et al., 2006). Violent offenders with an abusive history have also been shown to mistreat animals in their early childhood, suggestive of context independency (Agnew, 1998). We attribute this to a combination of consistent harm-oriented behaviors with low attack latencies and context independency, alike in both humans and SAL mice alike. Considering the criteria of construct validity, it seems that the SAL model reflects the neurobiological and physiological characteristics of instrumental violence in humans. This holds in particular for the low 5-HT levels, low basal heart rates and low glucocorticoid responses in the SAL mice (Section ‘SAL Mice as an Animal Model for Violence’). In view of this, we would argue that understanding the etiology
of violence, its prevention and treatment might profit from a mutual scientific exchange between human and rodent studies of aggression and violence in general.

**GENERAL CONCLUSIONS**

Through a comparative behavioral analysis of agonistic behaviors in the high-aggressive mouse lines SAL, TA and NC900, we have now identified an operational definition for violence. Differences between violence and adaptive aggression are qualitative, as established unanimously by studies using these rodents. The TA and NC900 lines are ‘hyper-aggressive’ strains that have proven useful as behavioral controls in the identification of the deviant forms of aggressive behavior in SAL mice. This comparison becomes especially important given the lack of similar behavioral features in toto in other rodent models. We therefore conclude that the SAL mice can be considered a reasonably valid animal model for human violence based on extensive similarities in the underlying behavioral and physiological symptomatology, etiology and putative neurobiological mechanisms.
