Observation of the Decays $\Lambda_b^0 \rightarrow \chi_{c1} p K^-$ and $\Lambda_b^0 \rightarrow \chi_{c2} p K^-$

R. Aaij et al. (LHCb Collaboration)

(Received 27 April 2017; published 8 August 2017)

The first observation of the decays $\Lambda_b^0 \rightarrow \chi_{c1} p K^-$ and $\Lambda_b^0 \rightarrow \chi_{c2} p K^-$ is reported using a data sample corresponding to an integrated luminosity of 3.0 fb$^{-1}$, collected by the LHCb experiment in $pp$ collisions at center-of-mass energies of 7 and 8 TeV. The following ratios of branching fractions are measured:

$$\frac{B(\Lambda_b^0 \rightarrow \chi_{c1} p K^-)}{B(\Lambda_b^0 \rightarrow J/\psi p K^-)} = 0.242 \pm 0.014 \pm 0.013 \pm 0.009,$$

$$\frac{B(\Lambda_b^0 \rightarrow \chi_{c2} p K^-)}{B(\Lambda_b^0 \rightarrow J/\psi p K^-)} = 0.248 \pm 0.020 \pm 0.014 \pm 0.009,$$

$$\frac{B(\Lambda_b^0 \rightarrow \chi_{c2} p K^-)}{B(\Lambda_b^0 \rightarrow \chi_{c1} p K^-)} = 1.02 \pm 0.10 \pm 0.02 \pm 0.05,$$

where the first uncertainty is statistical, the second systematic, and the third due to the uncertainty on the branching fractions of the $\chi_{c1} \rightarrow J/\psi \pi$ and $\chi_{c2} \rightarrow J/\psi \pi$ decays. Using both decay modes, the mass of the $\Lambda_b^0$ baryon is also measured to be $m_{\Lambda_b^0} = 5619.44 \pm 0.28 \pm 0.26$ MeV/$c^2$, where the first and second uncertainties are statistical and systematic, respectively.

DOI: 10.1103/PhysRevLett.119.062001

Since the birth of the quark model, it has been speculated that hadrons could be formed from multiquark states beyond the well-studied quark-antiquark (meson) and three-quark (baryon) combinations [1–3]. Using a six-dimensional amplitude analysis of the $\Lambda_b^0 \rightarrow \chi_{c1} p K^-$ decay mode, the LHCb Collaboration observed the $P_c(4380)^+$ and $P_c(4450)^+$ states [4,5], which are consistent with $uudc\bar{c}$ hidden-charm pentaquarks decaying to $J/\psi p$. Many phenomenological models describing the dynamics of these states have been proposed, including meson-baryon molecules [6–8], compact pentaquarks [9–11], and kinematic rescattering effects [12–16]. In particular, the authors of Ref. [12] noted the closeness of the $P_c(4450)^+$ mass to the $\chi_{c1} p$ threshold and proposed that, if the $P_c(4450)^+$ state is a rescattering effect, then it would not appear as an enhancement near the $\chi_{c1} p$ threshold in the $\Lambda_b^0 \rightarrow \chi_{c1} p K^-$ decay mode, an approach recently challenged in Ref. [17]. This Letter presents an initial stage in the investigation of this hypothesis by making the first observation of $\Lambda_b^0 \rightarrow \chi_{c1} p K^-$ and $\Lambda_b^0 \rightarrow \chi_{c2} p K^-$ decays and measurements of their branching fractions relative to the $\Lambda_b^0 \rightarrow J/\psi p K^-$ decay. Throughout this Letter, the inclusion of charge-conjugated processes is implied and the symbol $\chi_{cJ}$ is used to denote the $\chi_{c1}$ and $\chi_{c2}$ states collectively. All $\Lambda_b^0$ decay modes considered here proceed via the same quark-level process, whose dominant contribution is shown in Fig. 1. A measurement of the $\Lambda_b^0$ mass is also presented.

Previous measurements of the branching fractions of $B \rightarrow \chi_{cJ} K$ decays [18–20] have shown that the $\chi_{c2}$ mode is suppressed relative to the $\chi_{c1}$ mode, in agreement with the predictions from the factorization approach [21], although the suppression appears to be lessened when additional particles are present in the final state [22]. Studying the production of $\chi_{cJ}$ mesons in $\Lambda_b^0$ baryon decays will help to further test the factorization approach, as the additional spectator quark in the baryon decay may play an important role in modifying final-state interactions.

The measurements described in this Letter are based on a data sample corresponding to 1.0 fb$^{-1}$ of integrated luminosity collected by the LHCb experiment in $pp$ collisions at a center-of-mass energy of 7 TeV in 2011, and 2.0 fb$^{-1}$ at 8 TeV in 2012. The LHCb detector [23,24] is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, designed for the study of particles containing $b$ quarks.

FIG. 1. Feynman diagram of $\Lambda_b^0 \rightarrow J/\psi \Lambda^*$ and $\Lambda_b^0 \rightarrow \chi_{cJ} \Lambda^*$ decays, where $\Lambda^*$ refers to an excited $\Lambda$ baryon.
or $c$ quarks. The detector includes a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the $pp$ interaction region, a large-area silicon-strip detector located upstream of a dipole magnet with a bending power of about 4 Tm, and three stations of silicon-strip detectors and straw drift tubes placed downstream of the magnet. The tracking system provides a measurement of momentum, $p$, of charged particles with a relative uncertainty that varies from 0.5% at low momentum to 1.0% at 200 GeV/$c$. The minimum distance of a track to a primary vertex (PV), the impact parameter (IP), is measured with a resolution of $(15 \pm 29/p_T) \mu$m, where $p_T$ is the component of the momentum transverse to the beam, in GeV/$c$. Different types of charged hadrons are distinguished using information from two ring-imaging Cherenkov detectors. Photons, electrons, and hadrons are identified by a calorimeter system consisting of scintillating-pad and preshower detectors, an electromagnetic calorimeter, and a hadronic calorimeter. Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers. The online event selection is performed by a trigger, which consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage, which applies a full event reconstruction. The software trigger selects events that contain a pair of oppositely charged muons that form a vertex that is significantly separated from all PVs.

In the simulation, $pp$ collisions are generated using Pythia 8 [25] with a specific LHCb configuration [26]. Decays of hadronic particles are described byEvtGen [27], in which final-state radiation is generated using Photos [28]. The interaction of the generated particles with the detector, and its response, are implemented using the Geant4 toolkit [29] as described in Ref. [30]. The products of the $\Lambda_b^0$ decays are generated uniformly within the available phase space.

The $\Lambda_b^0 \to \chi_{cJ} p K^−$ and $\Lambda_b^0 \to J/\psi p K^−$ candidates are reconstructed via the decays $\chi_{cJ} \to J/\psi \gamma$ and $J/\psi \to \mu^+ \mu^−$. To separate signal from background, an offline selection is applied after the trigger, consisting of a loose preselection followed by a multivariate classifier based on a gradient-boosted decision tree (GBDT) [31].

The $J/\psi$ candidates are formed from two oppositely charged particles with $p_T > 550$ MeV/$c$, identified as muons and consistent with originating from a common vertex, but inconsistent with originating from any PV. The invariant mass of the $\mu^+ \mu^−\gamma$ pair is required to be in the range $[3000, 3170]$ MeV/$c^2$. The $\chi_{cJ}$ candidates are formed from a $J/\psi$ candidate and a photon with $p_T > 700$ MeV/$c$. Photons that are consistent with originating from a $\pi^0$ meson when combined with any other photon in the event are removed. The invariant mass of the $\mu^+ \mu^−\gamma$ combination is required to be in the range $[3400, 3700]$ MeV/$c^2$. In the following, the notation $[c\bar{c}]$ will be used to refer to the initial $J/\psi$ or $\chi_{cJ}$ candidate from the $\Lambda_b^0$ baryon decay, while the notation $m(J/\psi X)$ or $m(\chi_{cJ} X)$ denotes an invariant mass that has been calculated with a mass constraint applied to the $J/\psi$ or $\chi_{cJ}$ candidate.

The $\Lambda_b^0$ candidates are formed from a $[c\bar{c}]$ candidate and two good-quality oppositely charged tracks each with $p_T > 200$ MeV/$c$, identified as a proton and kaon. Both tracks are required to be significantly displaced from any PV. A kinematic fit [32] is applied to the $\Lambda_b^0$ candidate, with the $J/\psi$ and $\chi_{cJ}$ masses constrained to their known values [33], and the $\Lambda_b^0$ candidate constrained to point back to a PV. This has the effect of producing separated peaks for the two decay modes. The mass resolution for $\Lambda_b^0 \to \chi_{cJ} p K^−$ decays is lower compared to that for $\Lambda_b^0 \to \chi_{cJ} p K^+$ decays due to the wrong mass hypothesis of the $[c\bar{c}]$ candidate.

Contributions from $B^0 \to [c\bar{c}] K^+\pi^−$ ($B^+_s \to [c\bar{c}] \phi$, $\phi \to K^+K^−$) decays, where the $\pi^− (K^−)$ is misidentified as an antiproton, are suppressed by placing tighter particle identification requirements on the misidentified hadron for candidates with an invariant mass within $30$ MeV/$c^2$ of the $B^0$ ($B^+_s$) mass [33] when evaluated using $\pi^−$ or $K^−$ mass assignments for the antiproton candidates. Typical misidentification probabilities are $5\%$-$15\%$, dependent on the particle momentum [34]. In the $\Lambda_b^0 \to \chi_{cJ} p K^−$ samples, small contributions from $B^0 \to J/\psi K^+\pi^−$ or $B^+_s \to J/\psi \phi$ decays, where in addition to the misidentification the $J/\psi$ meson is combined with a random photon in the event, are removed by the requirement that $m(J/\psi K^+\pi^−)$ or $m(J/\psi K^+K^−)$ are within $30$ MeV/$c^2$ of the $B^0$ or $B^+_s$ mass. Additionally, $\phi \to K^+K^−$ decays are vetoed by removing all candidates where the invariant mass of the $pK^-$ combination is within $12$ MeV/$c^2$ of the known $\phi$ meson mass when the kaon mass is used instead of the proton mass. Further misreconstructed backgrounds are studied using a fast simulation package [35] and are found to have no peaking components in the invariant mass window of interest.

The GBDT is used to further suppress the combinatorial background. It is trained on a simulated sample of $\Lambda_b^0 \to \chi_{cJ} p K^−$ decays for the signal and candidates from data with $m(\chi_{cJ} p K^−)$ in the range $[5700, 5800]$ MeV/$c^2$ for the background. Twelve variables are used as input. The first of these is the $\chi^2$ value obtained from a kinematic fit with the $\Lambda_b^0$ candidate constrained to point back to a PV and a mass constraint applied to the $J/\psi$. In addition, for the signal mode, $\chi_{cJ}$ or $\chi_{cJ}$ mass constraints are applied, with the smaller $\chi^2$ values being used; note that this differs from the fit used to separate the mass peaks, which does not include a $\chi_{cJ}$ constraint. The remaining variables are the $p_T$ of the $\Lambda_b^0$ proton and kaon, the $\Lambda_b^0$ decay-length significance, the cosine of the angle between the momentum of the $\Lambda_b^0$ candidate and its displacement from the PV, the proton and kaon $\chi^2_{IP}$, defined as the difference in the vertex-fit $\chi^2$ of the PV when reconstructed with and without the considered particle, and the estimated probabilities that the two muons, kaon and proton, are correctly identified by the particle identification detectors.
Prior to the training, several modifications are made to the simulated samples to better match the kinematic distributions observed in data. First, the simulated $\Lambda_b^0 \to J/\psi p K^-$ events are weighted according to the six-dimensional amplitude model developed in Ref. [4]. Second, a multidimensional gradient-boosting algorithm [36] is used to weight the simulated $\Lambda_b^0 \to J/\psi p K^-$ decays such that the distributions of $\Lambda_b^0$ pseudorapidity, the number of tracks in the event, and the GBDT training variables (apart from those related to particle identification) match those observed in the preselected background-subtracted $\Lambda_b^0 \to J/\psi p K^-$ data sample. These weights are also applied to the simulated $\Lambda_b^0 \to \chi_c J p K^-$ samples. Finally, the simulated distributions of the particle identification variables for the muon, proton, and kaon candidates are resampled from data calibration samples ($D^+ \to D\pi^+$, $J/\psi \to \mu^+\mu^-$, $\Lambda \to p\pi^-$, and $\Lambda^+_c \to pK^-\pi^+$ decays) in bins of track $p_T$ and the number of tracks.

The optimal working point for the GBDT response is chosen by maximizing a figure of merit, $S/\sqrt{S+B}$, where $S = S_0 e$ and $B$ are the expected signal and background yields within $\pm 20$ MeV/c$^2$ of the known $\Lambda_b^0$ baryon mass [33], $S_0$ is the signal yield determined from data without any cut on the GBDT response, and $e$ is the relative efficiency of the GBDT selection, evaluated using the simulated sample. The $\Lambda_b^0$ mass sidebands from the data are used to estimate $B$. The same GBDT and working point are used for the $\Lambda_b^0 \to J/\psi p K^-$ normalization mode. The GBDT selection efficiencies are 78%, 75%, and 68% for the $\Lambda_b^0 \to \chi_c J p K^-$, $\Lambda_b^0 \to \chi_c p K^-$, and $\Lambda_b^0 \to J/\psi p K^-$ channels, respectively.

After applying the GBDT requirement, $(2.9 \pm 0.4)\%$ of the selected events contain multiple $\Lambda_b^0 \to \chi_c J p K^-$ candidates. In approximately 80% of these cases, the same $J/\psi p K^-$ combination is combined with an additional, unrelated, photon in the event. The results reported in this Letter retain all candidates and the reported branching fractions are corrected to account for this. The correction factor is $0.993 \pm 0.006 (0.986 \pm 0.009)$ for $\Lambda_b^0 \to \chi_c J p K^-$ ($\Lambda_b^0 \to \chi_c p K^-$) decays, which is evaluated using a combination of the simulated samples and pseudoexperiments. The larger width of the $\Lambda_b^0 \to \chi_c p K^-$ component leads to the larger uncertainty on the correction factor. For the selected $\Lambda_b^0 \to J/\psi p K^-$ sample, $(0.75 \pm 0.05)\%$ of the events have multiple candidates.

Extended unbinned maximum-likelihood fits are performed to the distributions of $m(\chi_{c1} p K^-)$ and $m(J/\psi p K^-)$ for the signal and normalization modes, respectively. The fit models consist of signal components, each described by the sum of two Crystal Ball (CB) functions [37] with a common mean and power-law tails on both sides, and a linear combinatorial background component. Because of the small $\chi_{c0} \to J/\psi \gamma$ branching fraction [33] the contribution from the $\chi_{c0}$ mode is negligible. Several parameters of the signal shapes are determined from fits to simulated samples. These include the tail parameters of the CB functions, the ratio of the widths of the two CB functions, and their relative normalizations. The $\Lambda_b^0 \to \chi_{c2} p K^-$ signal component is shifted to a lower mass in $m(\chi_{c1} p K^-)$ due to the $\chi_{c1}$ mass constraint. The signal and background yields, the gradient of the background shape, and the mean of each signal component are free parameters in the fit to data. In addition, the widths of the $\chi_{c1}$ and $\chi_{c2}$ components in the fit to $m(\chi_{c1} p K^-)$ are allowed to differ from simulation by a common scaling factor, while the width of the narrower CB function in the $\Lambda_b^0 \to J/\psi p K^-$ signal component is a free parameter in the fit to data. The results of these fits are shown in Fig. 2. The measured yields are $453 \pm 25$, $285 \pm 23$, and $29815 \pm 178$ for the $\chi_{c1}$, $\chi_{c2}$, and $J/\psi$ modes, respectively. The significance of each of the signal components in the fit to $m(\chi_{c1} p K^-)$ is calculated using Wilks’ theorem [38]. This gives statistical significance of 29 and 17 standard deviations for the decay modes with $\chi_{c1}$ and $\chi_{c2}$, respectively.

Simulated samples are used to determine, for each decay mode, the reconstruction and selection efficiency as a function of the Dalitz plot coordinates [39], $m^2(p K^-)$ and $m^2(|c\bar{c}|p)$. This approach focuses on the dimensions.

![FIG. 2. Fits to the (a) $\Lambda_b^0 \to \chi_{c1} p K^-$ and (b) $\Lambda_b^0 \to J/\psi p K^-$ invariant mass distributions. Data points are shown in black and the results of the fits are shown as solid blue lines. The components are $\Lambda_b^0 \to \chi_{c1} p K^-$ and $\Lambda_b^0 \to \chi_{c2} p K^-$ signal and combinatorial background (Comb).](image-url)
where the efficiency variation is expected to be largest whilst averaging over other dimensions in the phase space of $\Lambda_b^0 \to [c\bar{c}]pK^-$. This assumption is treated as a source of systematic uncertainty. The efficiency of each mode, $e_{[c\bar{c}]i}$, is due to geometric acceptance, reconstruction, and selection including the GBDT. The ratios of the phase-space-averaged values of these efficiencies are 0.182 ± 0.005 for $e_{\chi_{c1}/\psi}$, and 0.196 ± 0.005 for $e_{\chi_{c2}/\psi}$, where the uncertainties are due to the size of the simulated samples. This includes a correction factor for the $\chi_{cJ}$ decay modes to account for differences in the photon reconstruction efficiency between data and simulation [20,40].

An efficiency-corrected, background-subtracted yield is determined for each decay mode as $N_{\text{corr}}([c\bar{c}]pK^-) = \sum_i w_i / e_{[c\bar{c}]i}$, where the index $i$ runs over all candidates in the fit range. The $w_i$ are weights determined using the sPlot background-subtraction technique [41], which project out the signal component from the combined signal plus background densities using the $[c\bar{c}]pK^-$ invariant mass as a discriminating variable. The corrected yields are found to be about 99 700 ± 5300, 57 800 ± 4400 and 1 213 500 ± 7300 for the $\chi_{c1}$, $\chi_{c2}$, and $J/\psi$ decay modes, respectively, where the uncertainties are determined from the sum in quadrature of the event weights. Since these weights are determined from a fit in which all shape parameters are fixed, following the sPlot prescription, the effect on the yield uncertainty due to the statistical uncertainties on these parameters is not included. To quantify this, the unweighted fit is performed with the shape parameters fixed and then free, and the difference in quadrature of the uncertainties is found to be 1.5% of the yield for $\Lambda_b^0 \to \chi_{c1}pK^-$ decays and 2.1% for $\Lambda_b^0 \to \chi_{c2}pK^-$. A corresponding uncertainty is added in quadrature to that on the efficiency-corrected yield. The effect is negligible for the much larger $\Lambda_b^0 \to J/\psi pK^-$ signal.

The ratios of branching fractions are determined as

$$R_{1(2)} = \frac{B(\Lambda_b^0 \to \chi_{c12}pK^-)}{B(\Lambda_b^0 \to J/\psi pK^-)} = \frac{N_{\text{corr}}(\chi_{c12}pK^-)}{N_{\text{corr}}(J/\psi pK^-)} \times \frac{1}{B(\chi_{c12} \to J/\psi\gamma)}$$,

where the branching fraction of the $\chi_{c1} \to J/\psi\gamma$ ($\chi_{c2} \to J/\psi\gamma$) decay is taken to be $(33.9 \pm 1.2)\%$ ($(19.2 \pm 0.7)\%$) [33]. Figure 3(a) shows the distribution of $\Delta m + m_{J/\psi}$, where $\Delta m = m(\mu^+\mu^-) - m(\mu^+\mu^-)$ and $m_{J/\psi}$ is the known mass of the $J/\psi$ meson [33], while Fig. 3(b) shows $\Delta m + m_{J/\psi}$ for background-subtracted $\Lambda_b^0 \to \chi_{c1}pK^-$ candidates. Both distributions show clear enhancements at the known masses of the $\chi_{cJ}$ mesons.

The $\Lambda_b^0 \to \chi_{cJ}pK^-$ data sample is also used to make a measurement of the $\Lambda_b^0$ mass, $m_{\Lambda_b^0}$. The momenta of the particles are scaled to account for known miscalibration of the detector [42]. In addition, the separation between the $\Lambda_b^0 \to \chi_{c1}pK^-$ and $\Lambda_b^0 \to \chi_{c2}pK^-$ components of the $m(\chi_{c1}pK^-)$ spectrum is fixed to the known mass difference between the $\chi_{c1}$ and $\chi_{c2}$ mesons [33], to obtain a single measurement of $m_{\Lambda_b^0}$ using both decay modes. The mass fit is repeated after these changes, yielding $m_{\Lambda_b^0} = 5619.44 \pm 0.28$ MeV/c$^2$.

Systematic uncertainties on the ratios of branching fractions are assigned due to imperfect knowledge of the trigger efficiency and data-simulation discrepancies in the photon reconstruction as well as for uncertainties on the corrections applied to the simulated data (kinematic

![FIG. 3. Distributions of (a) $m(\chi_{cJ}pK^-)$ versus $\Delta m + m_{J/\psi}$, where $\Delta m$ is $m(\mu^+\mu^-) - m(\mu^+\mu^-)$ and $m_{J/\psi}$ is the known mass of the $J/\psi$ meson [33], and (b) $\Delta m + m_{J/\psi}$ for background-subtracted $\Lambda_b^0 \to \chi_{c1}pK^-$ (green circles) and $\Lambda_b^0 \to \chi_{c2}pK^-$ (magenta triangles) candidates (cands).]
which is taken from a previous LHCb study [45].

found to be small due to the mass constraints that are from the photon reconstruction (both 4.0%) and kinematic 2.0%, respectively.

effect of which is determined by repeating the analysis with uncertainties on the momentum scale (\(\pm\)).

signal and background components of the invariant mass fits the size of the simulated samples is determined from assigned as a systematic uncertainty. The uncertainty from treatment of multiple candidates (1.1%). The total systematic uncertainties on are due to the size of the simulated samples (1.2%) and the models are evaluated by repeating the analysis with weighting are.

The systematic uncertainties due to the trigger and photon reconstruction are taken from previous LHCb studies [20,40,43]. The uncertainties assigned due to the kinematic weighting are evaluated by repeating the analysis with alternative efficiency histograms that make use of a simplified three-dimensional weighting procedure with only the \(\Lambda^0_b\) pseudorapidity, \(\Lambda^0_b\) \(p_T\) and event track multiplicity. The uncertainty on the correction for multiple candidates is assigned as a systematic uncertainty. The uncertainty from the size of the simulated samples is determined from pseudoexperiments by varying the efficiency in each bin of each efficiency histogram within its uncertainties. The signal and background components of the invariant mass fits are replaced with the sum of two Gaussian functions and an exponential function, respectively, to estimate systematic uncertainties due to the choice of models.

The largest systematic uncertainties on \(R_1\) and \(R_2\) come from the photon reconstruction (both 4.0%) and kinematic weighting of the simulated samples (2.2% and 2.0%, respectively). For \(R_{2/1}\), the largest systematic uncertainties are due to the size of the simulated samples (1.2%) and the treatment of multiple candidates (1.1%). The total systematic uncertainties on \(R_1\), \(R_2\), and \(R_{2/1}\) are 5.2%, 5.4%, and 2.0%, respectively.

For the \(\Lambda^0_b\) mass measurement, systematic uncertainties are assigned due to the uncertainty on the momentum scale for charged-particle tracks, uncertainties on the \(\chi_{cJ}\) and kaon masses, energy loss in the material, miscalibration of the electromagnetic calorimeter, and the models for the signal and background components in the fit. The total systematic uncertainty (0.26 MeV/c\(^2\)) is dominated by the uncertainty on the momentum scale (0.24 MeV/c\(^2\)), the effect of which is determined by repeating the analysis with the momentum scaling parameter varied up and down by one standard deviation [42]. The uncertainty from the miscalibration of the electromagnetic calorimeter [44] is found to be small due to the mass constraints that are applied, as is the uncertainty on the energy loss in material, which is taken from a previous LHCb study [45].

In conclusion, the ratios of branching fractions are found to be

\[
R_1 = 0.242 \pm 0.014 \pm 0.013 \pm 0.009,
\]

\[
R_2 = 0.248 \pm 0.020 \pm 0.014 \pm 0.009,
\]

\[
R_{2/1} = 1.02 \pm 0.10 \pm 0.02 \pm 0.05,
\]

where the first uncertainty is statistical, the second systematic, and the third due to the uncertainty on the branching fractions of the \(\chi_{cJ} \rightarrow J/\psi\gamma\) decays. The values of \(R_1\) and \(R_2\) may be combined with existing measurements of \(B(\Lambda^0_b \rightarrow J/\psi pK^-)/B(B^0 \rightarrow J/\psi K^+(892)\)) [46] and \(B(B^0 \rightarrow J/\psi K^0(892)) [47]\) to obtain absolute branching fraction measurements. As the result in Ref. [47] assumes equal production of \(B^+ B^-\) and \(B^0\bar{B}^0\) pairs at the \(\Upsilon(4S)\) resonance, a correction is applied using the world average value of \(B(\Upsilon(4S) \rightarrow B^+ B^-)/B(\Upsilon(4S) \rightarrow B^0\bar{B}^0) = 1.058 \pm 0.024 [33]\), yielding \(B(\Lambda^0_b \rightarrow J/\psi pK^-) = (1.22 \pm 0.08) \times 10^{-3}\) and \(B(\Lambda^0_b \rightarrow J/\psi pK^-) = (3.01 \pm 0.21^{+0.42}_{-0.26}) \times 10^{-4}\), where the second uncertainty is due to the ratio of fragmentation fractions, \(f_{\Lambda^0_b}/f_d [48,49]\), and the first incorporates all other sources. This gives

\[
B(\Lambda^0_b \rightarrow \chi_{c1} pK^-) = (7.3 \pm 0.4 \pm 0.4 \pm 0.6^{+1.0}_{-0.6}) \times 10^{-5},
\]

\[
B(\Lambda^0_b \rightarrow \chi_{c2} pK^-) = (7.5 \pm 0.6 \pm 0.4 \pm 0.6^{+1.1}_{-0.6}) \times 10^{-5},
\]

where the third uncertainty is due to uncertainties on the \(\chi_{cJ}\) to \(J/\psi\), \(\Lambda^0_b \rightarrow J/\psi pK^-\) and \(B^0 \rightarrow J/\psi K^+(892)\) branching fractions and the fourth is due to \(f_{\Lambda^0_b}/f_d [48,49]\). These results show no suppression of the \(\chi_{c2}\) mode relative to the \(\chi_{c1}\) mode in \(\Lambda^0_b\) baryon decays, which is different to what is observed in \(B \rightarrow \chi_{cJ} K\) decays [18–20]. These decays will be useful for future investigations into the nature of the two pentaquark candidates observed by the LHCb Collaboration and provide further information on the applicability of the factorization approach in describing b-hadron decays to final states containing charmonium.

The \(\Lambda^0_b\) mass has also been measured and is found to be \(5619.44 \pm 0.28 \pm 0.26\) MeV/c\(^2\), where the first uncertainty is statistical and the second systematic. This result is combined with previous LHCb measurements from \(\Lambda^0_b \rightarrow [c\bar{c}]X\) decays [45,50,51] assuming that systematic uncertainties on the momentum scale and energy loss are fully correlated between the measurements while other sources of systematic uncertainties are uncorrelated. The procedure for the combination is the same as that used in Ref. [45]. This yields a new average value of \(5619.62 \pm 0.16 \pm 0.13\) MeV/c\(^2\), which supersedes previous combinations of these results.

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); MOST and NSFC (China); CNRS/IN2P3 (France); BMBF, DFG and MPG (Germany); INFN (Italy); NWO (Netherlands); MInSW and NCN (Poland); MEN/IFA (Romania); MinES and FASO (Russia); MinECo (Spain); SNSF and SER (Switzerland); NASU (Ukraine); STFC (United Kingdom); NSF (USA). We acknowledge the computing resources that are provided.
by CERN, IN2P3 (France), KIT and DESY (Germany), INFN (Italy), SURF (Netherlands), PIC (Spain), GridPP (United Kingdom), RRCKI and Yandex LLC (Russia), CSCS (Switzerland), IFIN-HH (Romania), CBPF (Brazil), PL-GRID (Poland) and OSC (USA). We are indebted to the communities behind the multiple open source software packages on which we depend. Individual groups or members have received support from AvH Foundation (Germany), EPLANET, Marie Skłodowska-Curie Actions and ERC (European Union), Conseil Général de Haute-Savoie, Labex ENIGMASS and OCEUV, Région Auvergne (France), RFBR and Yandex LLC (Russia), GVA, XuntaGal and GENCAT (Spain), Herchel Smith Fund, The Royal Society, Royal Commission for the Exhibition of 1851 and the Leverhulme Trust (United Kingdom).
