Abstract

p38 mitogen-activated protein kinase (MAPK) is thought to play a central role in acute and chronic inflammatory responses. Whether p38MAPK plays a pathogenic role in crescentic GN (GN) and which of its four isoforms is preferentially involved in kidney inflammation is not definitively known. We thus examined expression and activation of p38MAPK isoforms during anti-glomerular basement membrane (GBM) nephritis. Therefore, p38α conditional knockout mice (MxCre-p38αΔ/Δ) were used to examine the role of p38α in anti-GBM induced nephritis. Both wild type and MxCre-p38αΔ/Δ mice developed acute renal failure over time. Histological examinations revealed a reduced monocyte influx and less tubular damage in MxCre-p38αΔ/Δ mice, whereas glomerular crescent formation and renal fibrosis was similar. Likewise, the levels of pro- and anti-inflammatory cytokines such as TNF, IL-1 and IL-10 were similar, but IL-8 was even up-regulated in MxCre-p38αΔ/Δ mice. In contrast, we could detect strong down-regulation of chemotactic cytokines such as CCL-2, -5 and -7, in the kidneys of MxCre-p38αΔ/Δ mice. In conclusion, p38α is the primary p38MAPK isoform expressed in anti-GBM nephritis and selectively affects inflammatory cell influx and tubular damage. Full protection from nephritis is however not achieved as renal failure and structural damage still occurs.

Introduction

The MAPK family comprises a large group of protein kinases that respond for example to growth factors, osmotic stress, ultraviolet light and cytokines to regulate cell proliferation, differentiation and apoptosis [1–4]. MAPK regulate three major pathways: the Jun N-terminal kinases (JNKs), the extracellular signal-related kinases (ERKs) and the p38 MAPKs [5]. The p38MAPK pathway was initially identified in macrophages stimulated with lipopolysaccharide (LPS) and is present in many cells and tissues [6,7]. Pro-inflammatory cytokines can stimulate signal transduction through upstream kinases finally resulting in the phosphorylation and activation of p38MAPK. In turn, p38MAPK phosphorylates other kinases such as MAPKAPK2 (MK2) and activating transcription factor 2 (ATF2), which promote transcription of pro-inflammatory genes [8].

p38MAPKs are represented by four different isoenzymes: p38α, p38β, p38γ and p38δ [9–14]. Recently, the in vivo functions of the four isoenzymes could be partially defined. p38β, p38γ and p38δ are activated by distinct stimuli in vitro and are expressed in a more restricted manner. However, mice deficient in either one of these isoenzymes do not show a major phenotype [15,16]. In contrast, p38α plays an important role in tissue homeostasis and is widely expressed. In fact, p38α-deficient mice are not viable due to placental defects [17–19]. Recently, the use of mice conditionally deficient for p38α revealed specific roles of this isoenzyme in erythropoiesis as well as cardiac and liver regeneration [20].

Besides the developmental and regenerative function of p38α, a pro-inflammatory role has been proposed based on the pharmacological inhibition of p38α in several animal models of acute and chronic inflammation. Neutralization of p38α ameliorates pro-inflammatory cytokine production and tissue damage in mouse models of arthritis and other autoimmune disease models [21–25]. Moreover, p38α inhibitors were successfully used in a rodent model of crescentic glomerulonephritis (GN) [26,27]. Blockade of p38α was associated with reduction in infiltrating leukocytes and subsequent tissue damage. However, some of these previously used p38 inhibitors are not entirely specific for p38MAPK and block both the α- and β-isoform. Also, such inhibitors showed only minor and transient efficacy in a clinical trial in patients with rheumatoid arthritis [28].

Thus, it is yet unclear whether p38α indeed plays a specific role in crescentic GN and whether its inhibition could emerge as an
effective treatment for this rapidly progressive autoimmune disease. In this study, we thus used mice conditionally deleted for p38α and induced anti-glomerular basement membrane nephritis (anti-GBM) to test whether p38β is indeed responsible for tissue damage and leukocyte infiltration in kidneys affected by crescentic GN.

**Materials and Methods**

**Animals**

MsCre-p38α+/− mice and MsCre-p38β+/* mice (wild type littermates, genetic background C57Bl/6) were used for the experiments [20]. The deletion of the floxed alleles was induced by injecting 15 mg/kg polyinosinic-polycytidylic acid (Sigma-Aldrich) for 3 times intraperitoneally at week 10 of age. Genotyping of mice was performed in all mice. (Primers for genotyping are given in Text S1). All animal experiments were approved by the animal ethics committee of the government of Franconia (permit number 54-2532.1-11/10) and were carried out according to legal obligations defined by national animal protection laws.

**Induction of Anti-glomerular Basement Membrane (GBM) Glomerulonephritis (GN)**

Accelerated anti-GBM GN was induced in MsCre-p38α+/− and wildtype mice as described previously by Asgeirsdottir et al [29]. Briefly, 11-week-old mice were intraperitoneally immunized with 200 μg of sheep IgG (Sigma-Aldrich) dissolved in complete Freund’s adjuvant. After 6.5 days, mice received an intravenous injection of sheep anti-mouse GBM antibodies (50 mg/kg) and 100 μg of recombinant mouse tumor necrosis factor α (TNFα) in a total volume of 200 μl. Mice were sacrificed after indicated time periods and kidneys were perfused with 0.9% cold sodium chloride solution. One kidney was fixed in 4% formaldehyde for histology while the other kidney was divided into 3 parts and snap-frozen in liquid nitrogen and stored at −80°C for protein and mRNA analysis.

**Blood and Urine Examinations**

Blood urea nitrogen (BUN) was measured in serum at days 3, 7 and 14 after induction of anti-GBM GN. A quantitative enzymatic colorimetric BUN determination kit (Stanbio Laboratory, Boerne, Texas) was used according to the manufacturer’s protocol. To determine kidney function, mice were placed in single metabolic cages for 24 h the day before sacrifice. Creatinine was measured in serum and urine, and creatinine clearance was calculated according to the following formula: 

\[\text{crea}[\text{urine}] = \text{vol}[\text{urine}] / \text{crea}[\text{plasma}] \times \frac{\text{vol}[\text{urine}]}{\text{crea}[\text{plasma}]} \]

**Murine Podocyte Cell Culture**

Conditionally immortalized mouse podocyte cell lines were kindly provided by Prof. Karlhans Endlich (University of Greifswald). They were isolated from kidneys of Immorto-Mouse® mice (Charles River, St. Louis, MO) and carry a thermosensitive character, Boerne, Texas) was used according to the manufacturer’s instructions. For tissue damage and leukocyte infiltration in kidneys affected by crescentic GN.

**Primary Antibodies**

The following antibodies were used: rabbit anti-phospho p38MAPK (1:300; Cell Signaling Technology, Beverly, MA), rabbit anti-p38MAPK (1:300; Cell Signaling), rabbit anti-p38MAPKβ (1:300; Abgent, San Diego, CA), rabbit anti-p38MAPKγ (1:300; Cell Signaling), rabbit anti-p38MAPKδ (1:300; Abgent), rabbit anti-phospho MK2 (1:300; Cell Signaling), rabbit anti-MK2 (1:300; Santa Cruz Biotechnology, Santa Cruz, CA), rabbit anti-phospho ATF-2 (1:300; Cell Signaling), rabbit anti-ATF-2 (1:300; Santa Cruz), rabbit anti-phospho MKK3/6 (1:300; Santa Cruz), rabbit anti-MKK3 (1:300; Santa Cruz), rabbit anti-MK6 (1:300; Santa Cruz), rabbit anti-βActin (1:400; Sigma-Aldrich, St. Louis, MO). Antibodies against macrophages (anti-F4/80; 1:100; Serotec), neutrophils (1:300; MorphoSys), T lymphocytes (anti CD3; 1:100; NeoMarkers) and B cells (anti-CD20; 1:100; Sigma) were used for immunohistochemistry.

**Western Blotting**

In vitro cultured podocytes were lysed, lysates were mixed with 2 × SLB, boiled and separated by SDS-PAGE followed by transfer onto nitrocellulose membrane. After blocking with 10% Tris-buffered saline (TBS), 0.1% Tween 20 and 5% non fat dry milk, membranes were incubated with primary antibodies. Appropriate secondary horseradish peroxidase-conjugated antibodies (Dako, Glostrup, Denmark) and a chemiluminescent detection system (Pierce, Rockford, IL) were applied. The phosphorylated MAPKs were analyzed by normalization to total amount of kinase. For western blotting analysis of kidneys, protein lysates from frozen tissues were prepared. Tissues were dissolved in buffer containing urea (7M), glycine (10%), SDS (1%), Tris pH 6.8 (10 mM), phosphatase inhibitors (Sigma) and protease inhibitors (Roche, Mannheim, Germany). Each piece of tissue was homogenized with an Ultra Turrax and centrifuged for 15 min with 15,000 g at 4°C to get rid of tissue debris. The supernatant was transferred and protein concentration determined (BCA protein assay kit, Pierce). Western Blotting was performed as described above.

**Immunoprecipitation**

To determine p38 MAPK isoform phosphorylation in cultured podocytes and whole kidney tissues, immunoprecipitation was performed. For precipitation of cells, differentiated growth arrested podocytes were used after 15 min stimulation with TNFα (10 ng/ml). Cells were lysed in buffer (NP40 1%, sodium chloride 150 mM, Tris/HCl pH 7.5 25 mM, EDTA 1 mM, EGTA 1 mM, sodium fluoride 1 mM, β-glycerophosphate 1 mM, sodium pyrophosphate 2.5 mM, vanadate 1 mM, PMSF 1 mM) for 20 minutes on ice, followed by 10 min centrifugation at 10,000 g at 4°C. After determination of protein concentration, samples were mixed with 30 μl of immobilized protein A plus sepharose (Pierce) and antibody against phospho-p38 MAPK (1:50) and incubated at
4℃ for 2 h while gently shaking. After 3 washing steps with lysis buffer (3 min, 1.000 g, 4°C) the pellet was resuspended, boiled in 1× SLB and stored at −20°C. As controls two further immunoprecipitations were performed: One without lysate (negative control) and one with an IgG matched control antibody for phospho-p38 MAPK. Immunoprecipitation of kidney tissue taken at day 3 after injection of nephrotoxic serum was done by homogenizing the frozen tissue with an Ultra Turrax in buffer at 4°C as described above with addition of sodium dodecylsulfate (0.1%). After centrifugation (20 min, 10,000 g, 4°C) the supernatant was taken and the same procedure followed as described above. For western blot analysis each gel pocket was loaded with the full IP preparation or 50 μg of cell or tissue lysate.

Quantitative Real-time RT-PCR
RNA was isolated from cells and tissue withpeqGold TriFast reagent (Peqlab, Erlangen, Germany). RNA was isolated following standard laboratory procedures with chloroform and alcoholic precipitation. Purity was measured by photoelectrometry (Eppendorf). 1 μg of RNA was reversely transcribed using MuLV reverse transcriptase (Darmstadt, Germany) and random hexamer primers. Quantitative PCR amplifications were performed according to manufacturer’s protocol on an ABI Prism 7300 sequence detection system (Applied Biosystem). Primer sequences are given in Text S1. The RT² Profiler™ PCR Array System (SABiosciences, Frederick, MD, USA) for mouse chemokines and receptors was used to analyze the expression of a focused panel of genes. To this end we isolated RNA from five wild type and five MxCre-p38α mice 14 days after induction of anti-GBM induced nephritis. RNA isolation, cDNA preparation and PCR were done according to the manufacturers protocol. Thermal cycling was run in an ABI Prism 7300 sequence detection system (Applied Biosystem).

Histology
To determine the extent of crescent formation, tubular dilatation and scarring, paraffin embedded sections were stained with Sirius red, periodic acid-Schiff reagent (PAS) and hematoxylin and eosin (HE). To assess the percentage of crescents, all glomeruli of a section were counted. Afterwards the ratio of glomeruli affected by crescents to unaffected glomeruli was determined. The tubular damage index (0 to 3) was determined by assessing inflammation, fibrosis, tubular dilatation and tubular atrophy. Fibrosis scoring was performed semiquantitatively on Sirius red stained sections by evaluating the extent of fibrotic tissue vs. normal kidney tissue. All analyses were done with an Olympus CX41 microscope and a fence ocular in 200× magnification.

Immunohistochemistry
To determine immune cell infiltration of kidneys, serial sections (2 μm) of paraffin-embedded murine kidneys were used for immunohistochemistry. Slides for detection of T cells, neutrophils and macrophages were pretreated with recombinant protease K (Roche, Mannheim), whereas B-cell detection required no pretreatment. Non-specific binding was blocked by addition of a mixture (1:1 vol) of 10% goat serum and Roti-Immunoblock (Carl Roth, Karlsruhe, Germany). Sections were incubated with primary antibodies for 1 h at room temperature, followed by 30 min incubation with specific biotinylated immunoglobulin (Vector, Burlingame, CA), Vectastain ABC reagent (Vector) and 3,3’-diaminobenzidine (DAB, Sigma-Aldrich) as chromogen were used for final detection. Sections were counterstained with haematoxylin and eosin. Scoring of infiltrated immune cells was as follows: 20 lens coverages were counted all over the section (mark and cortex) and indicated in positive cells/mm².

Statistical Analysis
Results were analyzed for statistical differences either with one-way ANOVA and Tukey’s multiple comparison test or unpaired t-test. P≤0.05 was considered statistically significant. Data are presented as the mean±SEM.

Results
Selective Activation of p38α during Anti-GBM Nephritis
To determine whether p38MAPK signalling is active during crescentic GN, we used an established anti-GBM model and evaluated gene and protein expression during the disease course. To this end, we immunized mice with sheep IgG and then challenged the sensitized mice with sheep anti-GBM antibodies in conjunction with a single TNFα injection as previously described [29].

To demonstrate the functionality of our model, we performed histological analysis during different time points. As shown in Fig. 1A–D, injection of anti-GBM antibodies causes glomerular inflammation, glomerular crescent formation and tubular damage during the course of disease. We then analyzed expression of pro-inflammatory (TNFα, IL-1, IL-8) and anti-inflammatory (IL-10, TGFβ1) cytokines by quantitative real-time PCR (qPCR) to gain insight into the molecular changes during the inflammatory response (Fig. 1E). TNFα and IL-1β mRNA were up regulated during the first 7 days of disease. In contrast, IL-8 was found to be over-expressed during later stages of disease. We also found early up-regulation of the counter-regulatory cytokine IL-10 during anti-GBM induced nephritis. Interestingly, TGFβ1 was over-expressed at late stages of anti-GBM nephritis, which might correlate to crescent formation occurring at the same time.

We next analyzed the expression and activation of the p38MAPK pathway in this model. We therefore investigated early (35 min) and late (14 days) time points after injection of anti-GBM antibodies. First, we determined expression of the four known p30MAPK isoforms during the course of disease and could detect mRNA expression of all four p30MAPK isoforms in kidney lysates. Expression of all four isoforms was however not different during the disease course (data not shown). We then performed Western Blot analysis to confirm these findings. In support of the mRNA data, we could detect p30α, p30β, p30γ and p30δ in kidneys injected with anti-GBM antibodies. In line with results from qPCR, protein expression remained stable throughout the observation period (data not shown).

After assuring the expression of p30MAPK isoforms in anti-GBM induced nephritis, we asked whether the p30MAPK pathway is active during disease. As shown in Fig. 2, p30MAPK is phosphorylated and thus active throughout the observation period of anti-GBM induced nephritis. In addition, we found that the upstream kinase MKK3/6 and the downstream transcription factor ATF-2 is also phosphorylated indicating a functional p30MAPK signalling pathway in inflamed kidneys. To investigate, which p30MAPK isoform is preferentially activated during anti-GBM induced nephritis we analyzed the activation status of the p30MAPK isoforms using an activation-specific anti-phospho p30MAPK antibody. Interestingly, we found a clear activation of the α-isoform, but not the other p30MAPK isoforms (Fig. 2). Thus, p30MAPK is expressed and the only active p30MAPK isoform during anti-GBM induced nephritis is the α-isoform of p30.
Pro-inflammatory Cytokine Stimulation Specifically Activates p38α in Podocytes in vitro

We next investigated whether the p38MAPK pathway is functional in podocytes in vitro as these cells are critically involved in experimental nephritis and crescent formation [30,31]. As described previously, we therefore cultured undifferentiated and differentiated immortalized podocytes in vitro and stimulated them with TNFα [32]. Analysis of mRNA abundance of the four p38 MAPK isoforms and up- and downstream kinases revealed expression of the p38α and γ isoform as well as of MKK3, MKK6, MK2 and ATF-2 (Fig. S1A–B). These findings were supported by western blot analyses for the four isoforms (Fig. S1C): p38MAPK α and γ but not β and γ were detectable especially in differentiated podocytes. Next, we stimulated differentiated podocytes with TNF-α (10 ng/ml) to mimic an inflammatory condition. Western blot analyzes revealed enhanced signalling as early as 5 minutes (p-p38) to 10 minutes (p-MK2, p-ATF-2) after stimulation (Fig. S1D) suggesting that podocytes turn on p38MAPK signalling within minutes after cytokine exposure. We then addressed which of the p38MAPK isoform is activated. Immunoprecipitation using an activation-specific anti-phospho p38MAPK antibody (Fig. S1E) showed very clearly that only p38α

Figure 1. Functionality of the anti-GBM nephritis model and differential cytokine activation. Periodic acid-Schiff reagent (PAS) stain of a control kidney (A) and kidneys affected by crescentic GN over time are shown. BC = Bowmans capsule, CL = capillary loop, BM = basement membrane, Pod = podocyte, U = urinary space. Development of full crescents occurs within 14 days (B–D). Mice were sacrificed at indicated days (original magnification 20×). (E) Expression analyses of pro- (TNF-α, IL-1, IL-8) and anti-inflammatory (IL-10, TGFβ1) cytokines by qPCR in kidneys of control mice (white bars) and anti GBM-IgG treated mice (black bars). RNA was isolated from whole kidney lysates. Data are the mean value ± SEM (n = 4 for each time point).
doi:10.1371/journal.pone.0056316.g001
is detectable and thus active. Therefore, we conclude that pro-inflammatory stimuli preferentially activate the α-isof orm of p38 MAPK further supporting the use of MxCre-p38α/− mice in the anti-GBM induced nephritis model.

Effects of Conditional p38α Deletion on Anti-GBM Nephritis

First, we determined whether p38-gene deletion is evident in the p38α/− transgenic mice [20]. As represented in Fig. 3A there is a full knockout in tissue like spleen and liver and an approximately 50% deletion in the kidney. This is due to the MxCre-flox model and confirmed by other studies. Nevertheless this model is suitable for the investigation of anti-GBM nephritis, because the deletion occurs in areas, which are of interest in this study, e.g. vascular endothelium, glomerulus, distal convoluted tubule and collecting duct [33,34]. We found significant reduction of p38 phosphorylation in kidney lysates. In support of these data, downstream activation of MK2 was also strongly reduced. Indeed other MAP kinases like ERK and JNK are also activated in this model, but there is no further regulation detectable in the case of p38α/− (Fig. 3B). After p38α deletion, we induced anti-GBM nephritis as described above. We then determined survival of wild type and MxCre-p38α/− mice during the course of nephritis. Unexpectedly, we found no difference in the survival curve as shown in Fig. 3C. Also, serum urea levels increased both in wildtype (day 14: mean 66.6±18.3 mg/dl) and MxCre-p38α/− mice (day 14: mean 58.4±10.5 mg/dl; p = ns vs. wild type) similarly compared to healthy mice (Fig. 3D). Creatinine clearance revealed a decrease in both wildtype (154.4±29.70; n = 8) and MxCre-p38α/− (97.79±16.15; n = 9) mice (Fig. 3E) in contrast to healthy control mice (195.8±41.88; n = 4) suggesting impaired filtration function of the kidney. Thus, deletion of p38α does not protect from kidney failure in this nephritis model.

Deletion of p38α Ameliorates Tubular but not Glomerular Damage during Anti-GBM Nephritis

To determine the effects of the absence of p38α on structural damage during anti-GBM nephritis, we performed qualitative and quantitative histological scoring. We first analyzed tubular damage using a semi-quantitative score (Fig. 4A–C). Interestingly, p38α deletion significantly diminished tubular damage (mean score 0.6±0.1, p<0.05) as compared to wildtype mice (mean score 9.2±0.1). KIM-1 and Vimentin mRNA levels corroborated these data, as these are also markers of tubular damage (Fig. 4D–E). In both cases mRNA levels in the knockout mice were significantly reduced in contrast to wild type mice (KIM-1: wildtype 84.23±32.57; n = 4 vs. p38α/−/− 2.675±1.248; n = 4; Vimentin: wildtype 2.900±0.1732; n = 4 vs. p38α/−/− 1.375±0.3497; n = 4). Next, we analyzed glomerular crescent formation semi-quantitatively (Fig. 4F–H), revealing that similar amounts of glomeruli revealed crescent formation in wild type and MxCre-p38α/− mice (wild-type: mean 3.3±1.2% vs. MxCre-p38α/−: 4.2±1.5, p = ns). Likewise, no difference was observed for the fibrotic score (Fig. 4L–K). A slight tissue remodelling occurred in both wildtype and MxCre-p38α/− mice (wild-type: mean 1.4±0.1 vs MxCre-p38α/−: 1.6±0.2, p = ns). Although the glomerular deposition of mouse IgG is generally very low there is a remarkably decrease in the p38α/− group (0.082±0.0396; n = 5) in contrast to wildtype mice (0.25±0.035; n = 5; Fig. 4L–N). Thus, deletion of p38α protects from tubular damage in murine anti-GBM nephritis, whereas glomerular crescent formation and fibrosis is not affected.

Recruitment of Leukocytes to Kidneys in Anti-GBM Nephritis is p38α-dependent

We next analyzed the role of p38α in leukocyte recruitment into the kidneys affected by anti-GBM nephritis. We thus performed immune phenotyping of leukocytes in kidney sections using immunohistochemistry and quantitatively scored leukocyte infiltration. We first asked whether macrophage infiltration is p38α-dependent. F4/80 staining to detect macrophages clearly revealed a prominent infiltration in the kidneys of wildtype mice (mean 155.4±58.6 cells/mm²). In contrast, MxCre-p38α/− mice showed dramatically lower macrophage numbers (mean 25.7±3.3 cells/mm²; p<0.05 vs. wild type; Fig. 5A–C). A similar, although less strong difference was observed, when we evaluated the invasion of neutrophils. Whereas wild-type mice showed prominent neutrophil infiltration (mean 43.8±25.5 cells/mm²), this was less severe in MxCre-p38α/− mice (mean 26.2±6.6 cells/mm²; p<0.05 vs. wild type).
We then stained renal sections for B and T cells with anti-CD19 and anti-CD3 antibodies, respectively. Whereas we could not detect relevant B cell numbers in renal tissues, we clearly found T cell infiltration in wildtype mice injected with anti-GBM antibodies (mean 5.0 ± 1.5 cells/mm²). In contrast to macrophages and neutrophils, the number of T cells was not different among wild type and MxCre-p38α-/- mice (mean 9.1 ± 2.1 cells/mm², p = ns vs. wild-type; n = 9). These data indicate that p38α is critical for full activation of the innate immune response during anti-GBM nephritis.

Inflammatory Gene Expression during Anti-GBM Nephritis is Partially p38α-dependent

As we have observed a reduced renal influx of macrophages and neutrophils, we next determined whether the altered recruitment of leukocytes is associated with a change in the expression of pro- and anti-inflammatory cytokines in the affected kidneys. We therefore performed qPCR from renal tissue of wildtype and MxCre-p38α-/- mice 14 days after injection with anti-GBM antibodies. Whereas the mRNA expression of the pro-inflammatory cytokines TNF, IL-1β and IL-6 was unaltered by p38α-deletion, we detected a significant downregulation of IL-8 as well as up-regulation of IL-12 and IL-18 in p38α-deficient mice. In contrast, the expression of anti-inflammatory cytokines such as IL-10, IL-13 and TGFβ1 was not affected by p38α-deletion (Fig. 6A). In accordance with the data of macrophage staining, MCP-1 (monocyte chemoattractant protein 1) is clearly downregulated in MxCre-p38α-/- mice.

Because of the prominent phenotype of MxCre-p38α-/- mice revealing less macrophage and neutrophil influx as compared to wildtype mice, we analyzed mRNA expression of chemokines in more detail. As shown in Fig. 6B-C, chemokines associated with macrophage attraction were generally strongly down-regulated. Especially Ccl2, -4, -5 and -8 were massively suppressed in MxCre-p38α-/- mice.
Figure 4. Deletion of p38α ameliorates tubular but not glomerular damage during anti-GBM nephritis. (A) Semi-quantitative scoring of tubular damage. p38α deletion significantly diminishes tubular damage (mean score 0.6±0.1, p<0.05 vs. control; n = 7) as compared to wild type mice (mean score 0.9±0.01; n = 7). Tubules of wild type mice (B) are dilated, whereas tubules of MxCre-p38αD/Δ (C) mice are still tightly packed. (D) KIM-1 mRNA level is dramatically increased in wild type mice (wild type 84.23±32.57; n = 4 vs. p38αD/Δ, 2.675±1.248; n = 4) indicating high tubular damage. (E) Vimentin shows clear upregulation of its mRNA in wild type mice (2.900±1.732; n = 4) whereas it is reduced nearly to the baseline level in MxCre-p38αD/Δ mice (1.375±0.3497; n = 4). Dashed line indicates RNA base level of control mice. (F–H) Analysis of crescent formation during anti-GBM nephritis. Similar amounts of glomeruli revealed crescent formation in wild type (n = 6) and MxCre-p38αD/Δ mice (n = 6) (wild type: mean 3.3±1.2% vs. MxCre-p38αD/Δ: 4.2±1.5%, p = ns). (I–K) Fibrotic tissue remodelling occurred in both wild type (n = 7) and MxCre-p38αD/Δ mice (n = 7) (wild-type: mean 1.409±0.1122 vs. MxCre-p38αD/Δ: 1.615±0.1617, p = ns). Sirius red staining was performed 14 days after induction of anti-GBM nephritis. (L–M) p38α deletion affects the immune response to sheep IgG by decreased murine IgG depositions in the glomeruli.

doi:10.1371/journal.pone.0056316.g004

Figure 5. Recruitment of leukocytes to kidneys in anti-GBM nephritis is p38α-dependent. (A–C) F4/80 staining to detect macrophages clearly reveals a prominent infiltration in the kidneys of wild-type mice (mean 155.4±58.6 cells/mm²), whereas MxCre-p38αD/Δ mice show dramatically reduced macrophage numbers (mean 25.7±3.3 cells/mm², p<0.05 vs. wild type). (D–F) Wild type mice show prominent neutrophil infiltration (mean 43.8±5.5 cells/mm²). There is a similar infiltration but less severe in MxCre-p38αD/Δ mice (mean 26.2±6.6 cells/mm², p<0.05 vs. wild type). (G–I) In contrast to the other lymphocytes the number of T cells is not different among wild type (mean 5.0±1.5 cells/mm²) and MxCre-p38αD/Δ mice (mean 9.1±2.1 cells/mm², p = ns vs. wild-type). Staining was performed 14 days after induction of anti-GBM nephritis (n = 7/group).

doi:10.1371/journal.pone.0056316.g005
We also found that chemokines attracting neutrophils such as Cxcl1, -4, -5 and IL-8 were downregulated by p38α during anti-GBM nephritis. However, we could not detect such general changes regarding chemokines associated with lymphocyte influx (Fig. 6D). Taken together these data suggest that p38α deletion selectively blocks the expression of certain chemokines during anti-GBM nephritis, which are important for mononuclear cell influx to inflammatory sites. Despite these findings, pro-inflammatory cytokine production is not dramatically altered in these mice.

Discussion

The p38MAPK family consists of four isoforms (p38α, p38β, p38γ and p38δ) and it has so far been largely unknown, which of these isoforms is expressed and activated in renal inflammation. Our results indicate that the α-isofrom is the most important one since we demonstrated only significant p38α activation during anti-GBM induced nephritis in vivo, while the other three p38 isoforms were not activated. This study, we demonstrate accordingly a specific role of p38α in an experimental model of anti-GBM nephritis. Importantly, we demonstrate a preferential activation of p38α but not other p38 isoforms during the course of anti-GBM nephritis. Conditional deletion of p38α partially inhibited renal damage associated with anti-GBM nephritis by blocking leukocyte influx and tubular damage, while glomerular crescent formation and renal fibrosis were not affected.

Several lines of evidence suggested an important role for the p38MAPK pathway in the pathogenesis of crescentic GN. We also found that chemokines attracting neutrophils such as Cxcl1, -4, -5 and IL-8 were downregulated by p38α during anti-GBM nephritis. However, we could not detect such general changes regarding chemokines associated with lymphocyte influx (Fig. 6D). Taken together these data suggest that p38α deletion selectively blocks the expression of certain chemokines during anti-GBM nephritis, which are important for mononuclear cell influx to inflammatory sites. Despite these findings, pro-inflammatory cytokine production is not dramatically altered in these mice.

data from p38MAPK inhibition in rheumatoid arthritis (RA) patients [29]. RA patients did show a transient decrease of inflammatory parameters but relapsed soon after the initiation of p38 inhibitor therapy. It was also shown that p38β deficiency could lead to increased NF-kB activation upon pro-inflammatory stimulation, which may rescue some of the effects elicited by p38 signalling [25].

We did not study the effect of p38β inhibition in other cell types involved in glomerular injuries such as mesangial and endothelial cells in vitro. In the latter, deletion of p38α may cause other effects in inflammatory pathways than in podocytes. Moreover, podocytes in vivo may react different to inflammatory stimuli in terms of p38 isoform activation than in an artificial in vitro culture system, which should be addressed in future studies. Alternatively, p38β may not be of major importance for glomerular inflammation and scarring. Indeed, recent evidence proves against a major role of p38 in the pathogenesis of rodent ANCA-mediated glomerulonephritis [41].

An explanation for the selective phenotype induced by p38β-deletion in anti-GBM induced glomerulonephritis emerges when looking more closely at the histological changes in the kidneys and cytokine expression profiling. Whereas glomerular crescent formation and interstitial scarring were not affected by p38β-deletion, suggesting that the fibrotic response in the anti-GBM GN model is not dependent on p38β, a significant amelioration of tubular damage was observed by us. The latter is in agreement with previous studies using p38 inhibitors [27]. Reduced tubular damage was associated with reduced leukocyte migration into the kidneys. Especially macrophage and neutrophil infiltration was significantly reduced, while T cell infiltration was comparable to wild type mice injected with anti-GBM antibodies.

Interestingly, p38α is the dominant p38MAPK isoform expressed and activated in macrophages and podocytes, which are regarded as crucially involved in the pathogenesis of crescentic glomerulonephritis. Moreover, we could not detect any reduction of renal expression of several pro- and anti-inflammatory cytokines such as TNF, IL-1, IL-6, IL-10 and TGFβ1. In contrast, we could even detect increases in renal mRNA expression of IL-12 and IL-18 indicating that p38β over time may also have a regulatory activity to limit inflammation in addition to its well-known pro-inflammatory role.

The reduced macrophage and neutrophil immigration into inflamed kidney tissue could be due to different chemokine expression. In fact, while chemokines responsible for lymphocyte influx were not generally altered, we could detect massive down-regulation of macrophage and neutrophil- attracting chemokines such as CCL2, -4, Cxcl1, -4 and others. The latter finding may therefore explain the reduced influx of neutrophils and cells of the monocyte/macrophages into the kidneys during anti-GBM induced nephritis. However, these potentially positive effects did not translate into a major clinical amelioration of the experimental model.

In conclusion, p38β deletion selectively reduces inflammatory cell influx and tubular damage in murine anti-GBM nephritis but does not affect the formation of glomerular crescents and renal fibrosis. Consequently, full clinical and histological protection could not be achieved. Inhibition of p38α may therefore not be a promising strategy for the treatment for crescentic GN. Future studies could investigate why crescent formation and renal fibrosis can occur when macrophage infiltration is virtually absent.

Supporting Information

Figure S1 Pro-inflammatory cytokine stimulation specifically activates p38α in podocytes in vitro. Analyses of the mRNA expression of the four 38MAPK isoforms and up- and downstream kinases in proliferating (A) and differentiated (B) podocytes reveal expression of the p38α and γ isoform as well as of MKK3, MKK6, MK2 and ATF2. (C) Western blot analyses of the four p38MAPK isoforms support the findings of qPCR. (D) Protein was extracted from TNF-stimulated (10 ng/ml) differentiated podocytes and analysed for p38MAPK pathway activation using phospho-specific antibodies. (E) Immunoprecipitations (IP) were performed with buffer only (-) or with kidney lysates and anti-phospho p38MAPK antibody, or with kidney lysates using an isotype-matched control antibody (Iso). IPs and positive control lysate (+) were separated by SDS-PAGE, blotted onto nitrocellulose and probed with specific antibodies against p38 isoforms (arrows). HC: heavy chain of the precipitating antibody. (TIFF)
