Abstract

Background: Breast cancer screening is offered to *BRCA1* and *BRCA2* mutation carriers from the age of 25 years because of their increased risk of breast cancer. As ovarian cancer screening is not effective, risk-reducing salpingo-oophorectomy (RRSO) is offered after child bearing age. RRSO before menopause reduces the breast cancer risk as well as breast density. It can be questioned whether after premenopausal RRSO, the intensive breast cancer screening program needs modification.

Methods: We evaluated the effectiveness of breast cancer screening by clinical breast examination (CBE), mammography, and MRI in a population of 88 *BRCA1* and 51 *BRCA2* mutation carriers who had RRSO before the age of 52. Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated for each screening modality.

Results: During 422 women years, 14 breast cancers were diagnosed; 2 prevalent, 10 screen detected and 2 interval breast cancers (12 in *BRCA1* and 1 in *BRCA2* mutation carriers). Sensitivity, specificity, PPV, and NPV for the combined screening were 85.7%, 97.6%, 30.0%, and 99.8%, respectively. No tumours were found with CBE, MRI had a sensitivity of 60.0% and mammography of 55.6%. Of all the tumours, 60% were node positive.

Conclusion: Effectiveness of CBE and mammography was comparable to earlier findings. MRI screening seemed less effective than earlier findings. After RRSO, the breast cancer risk in *BRCA1* and *BRCA2* mutation carriers is still high enough to justify intensive breast cancer screening with MRI and mammography.

Introduction

Breast cancer is the most common cancer in women and the lifetime risk of developing breast cancer for individual women in western countries is approximately 12 – 13% (1). Women with a family history of breast and/or ovarian cancer can have substantially higher risks (42). For women with a proven *BRCA1* or *BRCA2* mutation, life time risk can reach up to 65 – 80% for breast cancer and 45% for ovarian cancer by the age of 70 (5,6). In the Northern Netherlands we found a cumulative breast cancer risk of 71.4% (95% CI 67 – 82%) for *BRCA1* mutation carriers and 87.5% (95% CI 82 – 93%) for *BRCA2* mutation carriers by age of 70. For ovarian cancer these risks were 58.9% (95% CI 54 – 64%) and 34.5% (95% CI 25 – 44%), respectively (4).

Female mutation carriers are counselled on different risk reducing strategies, e.g. screening or prophylactic surgery. Prophylactic mastectomy strongly reduces the breast cancer risk, with about 90% at the age of 70 when conducted at the age of 38 years (183,244). Intensive breast cancer screening in mutation carriers consists of annual MRI, mammography, and clinical breast examination (CBE) and can reach a sensitivity of more than 90% in finding early stage breast cancer in mutation carriers (163,170,173,175,245). For ovarian cancer, it was recently shown that current screening protocols are ineffective in detecting early stage ovarian cancer in mutation carriers and the only effective strategy to prevent ovarian cancer death is a risk reducing salpingo-oophorectomy (RRSO), which is eventually chosen by approximately 70% of these women (27,28,246,247).

When this procedure is performed before the age of 50 years, the risk of breast cancer is also reduced, with up to 50%, depending on the timing of RRSO (31). Nevertheless, breast cancer screening before the age of 50 is indicated for women with a breast cancer risk that is three times higher than the population risk (159,248). *BRCA1* and *BRCA2* mutation carriers continue to receive the same three modality breast screening program after RRSO as they had before.

Intensive breast cancer screening combining MRI, mammography, and CBE was proven to be effective in women at high risk for breast cancer (163,170,173,175). One of the reasons that MRI was introduced in the screening program is that mammography is less effective in younger premenopausal women with higher breast density, as is the case in *BRCA1/2* mutation carriers. We hypothesize that the breast cancer screening protocol might need adaptation in women after RRSO, because of the lower breast cancer incidence and the lower breast density after surgical menopause. The aim of this study is therefore to determine the effectiveness of breast cancer screening after RRSO in *BRCA1/2* mutation carriers.

Materials and methods

Study population

To determine the effectiveness of breast cancer screening in *BRCA1/2* mutation carriers after RRSO, a retrospective cohort study was performed in *BRCA1* or *BRCA2* mutation carriers who underwent a RRSO. All women who were younger than 52 years of age at RRSO (which is the mean age at menopause the Netherlands) were included. Results from subsequent breast cancer screening visits at the family cancer clinic from the University Medical Center Groningen (UMCG) between January 1995 and the end of September 2009 were analysed. Women needed to have at least one breast eligible for screening. Women with uni- or bilateral breast conserving therapy were included. The use of hormonal replacement therapy (HRT) was recorded and this was not an exclusion criterion. Women in whom ovarian cancer was diagnosed during RRSO were not included in the study.

Surveillance protocol

In our family cancer clinic, RRSO was initially an option from the age of 35 – 40 years in *BRCA1* mutation carriers and from the age of 40 – 45 years in *BRCA2* mutation carriers. As of 2007, counselling has moved toward a specific advice to have RRSO around the age of 40, because ovarian screening appeared not effective in reducing ovarian cancer death (27,28). However, the actual timing of this decision depends on many personal circumstances such as previous breast cancer, marital status, previous or planned pregnancies, and mental acceptance of this definitive procedure. The operative procedure is a day care surgical procedure, performed by laparoscopy (35).

As of 1995, annual clinical breast examination (CBE) by oncologic surgeons and nurse practitioners was performed together with annual mammography from the age of 25. From 1999, annual MRI was added to the protocol in a part of our population that participated in the MRISC study (163,164). After 2005 it is advised to screen *BRCA1/2* mutation carriers with annual CBE and MRI from age 25 till 60, to which mammography is added from age 30 onwards (159,248). At our centre, MRI and mammography imaging is ideally performed alternating, i.e. with a 6 month interval.

Variables and endpoints

Information on date of birth, mutation status, personal oncologic history, date of RRSO, and HRT use were collected for all women. For previous breast cancers, we collected information about age at diagnosis and therapy. We reviewed every visit where CBE, mammography and/or MRI was performed. For all these visits, the reason for visiting (screening or interval visit due to signs or symptoms), the performed diagnostic procedures and the outcomes of these investigations were collected. The result of a CBE consult is considered possibly malignant in case of referral for further investigation. The results of mammography and MRI screening are scored in a standardized way, according to the Breast Imaging Reporting and Data System (BI-RADS) classification. BI-RADS categories vary between 0 and V and BI-RADS category III or higher are considered abnormal and indicate further analysis by ultrasound, MRI and/or tissue sampling (249-251).

When additional diagnostic procedures were performed, the type of procedure and the findings were noted. Findings could be “no malignancy” (when no malignancy was found at the additional diagnostic procedures), “suspect for malignancy” (when more additional investigation was necessary), and “malignancy” (as confirmed by biopsy). For each new breast cancer, tumour size in millimetres and the presence or absence of lymph node metastases in the (sentinel) axillary lymph nodes were noted.

Data collection

All relevant data were retrieved from the patients' hospital file. Physician's letters, pathology reports, and imaging reports were used to collect detailed information about above mentioned variables and endpoints as defined below. Data from all consecutive screening visits after RRSO were entered into an SPSS database. Protection of the patient's identity was guaranteed by a patient identification number. Those numbers were only retraceable to an individual woman when entered in the hospital database, which is only accessible for medical staff from the hospital, having a personal account. Complying with Dutch law, no further Institutional Review Board approval was needed.

Statistical analysis

Duration of follow-up was calculated for each woman. Follow-up time was calculated from the date of RRSO to the following endpoints: date of prophylactic mastectomy, date of ablation or date of last screening visit. Newly detected

malignancies were defined as prevalent, screen-detected, or interval cancers. Women were assigned to two groups, based on their mutation (*BRCA1* or *BRCA2*). Characteristics of women are presented with median and range when they are continuous variables. For the other variables numbers are given and percentage for each mutation group. Differences between groups were calculated with the Kruskal Wallis test for continuous variables and χ^2 tests for the percentages within mutation groups. To compare the three different screening modalities, we calculated the sensitivity, specificity, PPV, and NPV of each screening modality. For these four outcomes, 95% confidence interval (95% CI) was calculated with the Wilson score interval method. For MRI and mammography, calculations were made for BI-RADS III and IV as cut off point for a positive (suspect) test. Statistical analyses were performed using the software of SPSS 16.0 for Windows and the VassarStats website (252).

Results

Population characteristics

Of all the mutation carriers who were screened at the UMCG after RRSO during the study period, 139 women met our inclusion criteria; 88 (63.3%) *BRCA1* mutation carriers and 51 (36.7%) *BRCA2* mutation carriers (Table 2.1). *BRCA1* mutation carriers had a median age at RRSO of 40.5 years (range 30–51 years) and *BRCA2* mutation carriers had a median age of 42 years (range 33 – 51 years). Of all women, 18% had a history of breast cancer, *BRCA1* mutation carriers more often than *BRCA2* mutation carriers (22.7% and 9.8%, respectively, $p = 0.081$). Of all women, *BRCA1* mutation carriers reported significantly more often breast cancer before and at the age of 45 years than *BRCA2* mutation carriers (80.0% and 40.0%, respectively, $p = 0.034$).

Screening visits and events during follow-up

The total follow-up in this study was 5064 months (422 women years). The median follow-up was 24.0 months per woman (range 2 – 236 months). Women were censored because of preventive mastectomy ($n = 32$, 23.0%), breast cancer ($n = 2$, 1.4%), referral to another hospital ($n = 7$, 5.0%) or loss to follow-up ($n = 10$, 7.2%), the other women were still in screening after the end of our study (Table 2.2). In the women for whom screening ended after detection of breast cancer, one underwent mastectomy and one did not undergo further screening after being diagnosed with metastases after breast cancer in history.

Malignancies after RRSO

In a total of 1,146 hospital visits, 1,191 screening modalities (CBE, MRI or mammography) were performed in 422 women years. During the total screening period, 14 new breast cancers were detected: 12 new tumours and 2 prevalent tumours, both within 6 months after RRSO. The median time between RRSO and detection of a new tumour was 16.5 months. Three patients with a new breast cancer had a history of breast cancer before RRSO. All of the 3 were contra-lateral new breast cancers, there were no local recurrences. In 6 of the 10 invasive cancers the lymph nodes were positive. One of the 2 interval cancers was node positive. Of the 14 women who were diagnosed with breast cancer after RRSO, 5 used HRT. One of these breast cancers was an interval tumour.

Performance of the screening methods

The performance of the three screening modalities is summarized in Table 2.3. The overall sensitivity of the breast cancer screening program is 85.7%. Two tumours were interval cancers. No tumours were found by CBE (*Table 2.3*). This gives CBE a sensitivity of 0%, a specificity of 97.7%, a PPV of 0%, and a NPV of 98.1. In 9 women with breast cancer after RRSO, mammography screening was conducted and 5 of the 9 cancers were identified by mammography. This gives mammography a sensitivity of 55.6%, a specificity of 98.4%, a PPV of 50.0%, and a NPV of 98.8%. In 10 women with breast cancer after RRSO MRI screening was conducted, 6 of these cancers were identified by MRI. This gives MRI a sensitivity of 60.0%, a specificity of 95.9%, a PPV of 35.3%, and a NPV of 98.5%.

Of the 2 interval tumours, the first (20 mm, node positive) was detected 5 months after screening CBE. Mammography screening had not yet been performed. This was in 1999 and MRI was not yet part of the screening protocol at that time. Five years after diagnosis, this patient died of metastatic disease after a relapse in the mastectomy scar. The second interval cancer (11 mm, node negative) was detected by the patient herself 2 weeks after a negative CBE screening. MRI had not been conducted and the last mammography was 17 months before the new tumour was found.

Table 2.3: Performance of the screening tests

	Cancer present	Cancer absent	Total
CBE: 11 cancers (2 interval), 9 invasive, 2 DCIS			
Positive	–	13	13
Negative	11	559	570
Total	11	572	583
Sensitivity: 0% (95% CI 0 – 32%)		PPV: 0% (95% CI 0 – 28%)	
Specificity: 97.7% (95% CI 96 – 99%)		NPV: 98.1% (95% CI 97 – 99%)	
Mammography BI-RADS \geq III: 9 cancers (no interval), 7 invasive, 2 DCIS			
Positive	5	5	10
Negative	4	316	320
Total	9	321	330
Sensitivity: 55.6% (95% CI 23 – 85%)		PPV: 50.0% (95% CI 20 – 80%)	
Specificity: 98.4% (95% CI 96 – 99%)		NPV: 98.8% (95% CI 97 – 100%)	
MRI BI-RADS \geq III: 10 cancers (no interval), 7 invasive, 3 DCIS			
Positive	6	11	17
Negative	4	257	261
Total	10	267	278
Sensitivity: 60.0% (95% CI 27 – 86%)		PPV: 35.3% (95% CI 15 – 61%)	
Specificity: 95.9% (95% CI 93 – 98%)		NPV: 98.5% (95% CI 96 – 100%)	
Total screening: 14 cancers (2 interval), 11 invasive, 3 DCIS			
Positive	12	28	40
Negative	2	1149	1151
Total	14	1177	1191
Sensitivity: 85.7% (95% CI 56 – 98%)		PPV: 30.0% (95% CI 17 – 47%)	
Specificity: 97.6% (95% CI 97 – 98%)		NPV: 99.8% (95% CI 99 – 100%)	

Abbreviations: DCIS is ductal carcinoma in situ; PPV is positive predictive value; NPV is negative predictive value.

Screening visits and additional investigation

Of the 139 women who attended screening after RRSO, 127 women had at least one screening CBE, 117 women had at least one screening mammography and 109 women had at least one screening MRI (Table 2.4). The total number of screening investigations was highest for CBE (583), and lowest for MRI (278). CBE generated the least additional diagnostic procedures, 3% of the screening visits led to additional research. For MRI, 21% of the screening visits led to additional research and for mammography, 14% of the screening visits led to additional research.

In the study period, a total of 27 invasive diagnostic procedures (15 fine needle aspirations and 12 biopsies) were conducted, also most after MRI. Most additional diagnostic procedures were performed by using ultrasound (64 times).

Table 2.4: Screening visits and additional investigation

Screening modality	Visits	CBE	Mammography	MRI	Ultrasound	FNA	Biopsy	Total
CBE (n = 127)	583	4	2	–	7	2	2	17
Mammography (n = 117)	330	2	3	2	31	3	4	45
MRI (n = 109)	278	5	4	5	27	10	6	57
Total	1191	11	9	7	64	15	12	118

Abbreviations: CBE is clinical breast examination, MRI is magnetic resonance imaging, FNA is fine needle aspiration.

While no new cancers were found with CBE, CBE was carried out as additional investigation 11 times. Of the tumours found during the screening period, 5 were palpable when CBE was carried out after suspect findings at mammography or MRI. In 3 of these cases, the women had had a negative CBE screening in the month before the suspect findings.

When screening consisted of MRI and mammography, 43 screening visits were needed to find one new breast cancer. When CBE was added to the screening, 85 screening visits were needed to find one new breast cancer.

Discussion

In this group of 139 *BRCA1/2* mutation carriers who had had RRSO at a premenopausal age and were under surveillance at our Family Cancer Clinic, 14 breast cancers were detected in 14 women during 442 women years. There were 2 prevalent, 10 screen detected and 2 interval breast cancers. The program sensitivity was 85.7% and the specificity 97.5%. For the individual screening modalities, the sensitivity for CBE was 0% (95% CI 0 – 32.1%), for mammography 55.6% (95% CI 22.7 – 79.9%), and for MRI 60.0% (95% CI 27.4 – 86.3%). Of all these cancers, 70% was high grade (III) and 60% of the tumours were node positive.

The program sensitivity of screening with MRI, mammography, and CBE was 85.7% (95% CI 56.2 – 97.6%). Earlier studies on screening effectiveness in women at high risk of breast cancer found sensitivities varying from 91.1% to 97.7%, which seems to be higher (163,170,173,175). Only one study on the long-term effectiveness of the MRISC study found a total program sensitivity of 86.6% (164). The study population in these previous studies was more diverse, consisting of pre- and

postmenopausal women. Also, their studies contained mutation carriers, but also women at high risk for breast cancer without mutation. In our study, all women were postmenopausal after premenopausal RRSO and they were all mutation carriers. These factors may have contributed to the differences in effectiveness.

Both Kriege *et al.* and Rijnsburger *et al.* present results of the MRISC study. Of the 2,275 participants in these studies, 148 were from our family cancer clinic (164). Kriege *et al.* noted that 19% of the mutation carriers had RRSO in history (163). The amount of women analysed in both the MRISC study and our study is probably small.

A main factor that might have contributed to the lower sensitivity of our surveillance program is that we evaluated the program sensitivity of the screening over a period of 14 years (1995 – 2009) during which screening guidelines changed several times. MRI was offered from 1999 to a subset of women as part of the MRISC study, and as of 2005 it is offered to all women at high risk. One interval cancer was found in 1999. Excluding this tumour from the analysis, would increase the program sensitivity of our screening from 85.7% to 91.7%, which is in the range that can be expected. Another consideration is that the four series mentioned are prospective studies with a strict screening protocol in which every woman receives MRI, mammography, and CBE at regular intervals (163,170,173,175). In daily practice, many factors may influence the regularity of the screening visits. Planning MRI, mammography, and CBE on the first visit is sometimes difficult because of agenda and capacity issues, women do not always attend appointments, or there may be contra-indications for MRI scanning. It is reasonable to assume that the second interval cancer is related to “protocol deviances.” This interval cancer was detected by the patient herself, two weeks after a negative CBE screening, and her last mammography was 17 months before the new tumour was found. Though this woman was in screening from 2005 to 2007, she was not screened by MRI.

For the separate screening modalities, the sensitivity of 0% (95% CI 0 – 32.1%) for CBE found in our study was comparable to sensitivities of 9.1 – 17.8% found in other studies (163,170). In general, CBE is considered to have no additional benefit over mammography, whereas it does increase the false positive rate (253,254). When CBE was excluded from program sensitivity analyses, sensitivity did not change. This would mean exclusion of 538 CBE screening visits in which no new tumours were detected. Three of the new tumours found by imaging were palpable at diagnosis (CBE was conducted as additional research), while CBE screening within the month before diagnosis was negative. Also, CBE has proven to be useful in detecting loco-regional recurrences and contralateral

breast cancer in an early stage in women with breast cancer in history (e.g. after mastectomy, breast conserving therapy, and radiotherapy) (255). This indicates that CBE should not be eliminated from our post-RRSO screening protocol, especially in women with previous breast cancer.

The sensitivity of 55.6% (95% CI 22.7 – 79.9%) for mammography was not significantly different from sensitivities of 32 – 40% reported in previous studies (163,170,173,175). Long-term follow-up in the MRISC study revealed a sensitivity for mammography of 25% in *BRCA1* mutation carriers (164). This is much lower than the sensitivity found in our study, while the majority of tumours we found, were also in *BRCA1* mutation carriers. Due to the lower breast density after RRSO, we expected that the sensitivity of mammography in our population would be higher than in other high risk screening studies. The sensitivity of mammography we found was indeed higher than previously reported though the difference was not significant. This may be due to small numbers, or to the fact that about 47% of the women used HRT after RRSO, which is known to preserve breast density in postmenopausal women (256).

The sensitivity of 60.0% (95% CI 27 – 86%) for MRI in our study was lower (though not significantly) than the sensitivities for MRI reported in previous studies, ranging from 71.1 to 77.0% (163,170,175) and significantly lower than the sensitivity of 90.7% for MRI found by Kuhl *et al.* (173). It is reasonable to suppose that the effectiveness of MRI screening in daily practice is less than the performance of MRI screening in prospective trials. At our centre, MRI software, protocols, and scanners evolved in the past years. It is likely that MRI sensitivity will improve in the future along with experience and further improvement of MRI technology. Another issue is that, 2 of the 4 tumours that were false negative on MRI were full ductal carcinoma *in situ* (DCIS). Most tumours missed on MRI in the MRISC study were also DCIS, which indicates that MRI is significantly less reliable in detecting DCIS (254). This is illustrated by the fact that for invasive tumours only, MRI sensitivity in our study is 75%, which lowers to 60.0% (95% CI 27.4 – 86.3%) when DCIS are included. Rijnsburger *et al.* found an MRI sensitivity of 66.7% for *BRCA1* mutation carriers and 69.2% for *BRCA2* mutation carriers, which was significantly higher than the sensitivity of 25% they found for mammography. In addition, they showed that MRI enabled the detection of breast tumours in a more favourable stage than mammography. They suggest that MRI screening should be considered biannually in certain categories (164).

In our study, tumour size was also comparable to other studies, with 83.3% of the tumours after RRSO being smaller than 20 mm, compared to percentages ranging from 75 to 94% in other studies. However, 60% of the tumours in our

study were node positive, while others found percentages of 15.4 – 36.0% (163,170,173,175). These findings need further evaluation.

This is the first study on the effectiveness of breast cancer screening with CBE, mammography, and MRI, in *BRCA1/2* mutation carriers who had undergone RRSO at premenopausal age, conducted in daily practice and not in the context of a clinical trial. It is an interesting finding that MRI sensitivity in this study was slightly lower than MRI sensitivity in earlier trials. The question is if this difference is caused by protocol deviances in general practice or by effects generated by RRSO. Also, mammography sensitivity seems to be higher after RRSO than before. This might be caused by lower breast density after RRSO, but this should be evaluated during long term follow-up. We used the number of new tumours detected by screening to evaluate the effectiveness of the surveillance program. Eventually, the purpose of screening is to increase survival after breast cancer. For evaluating the effect of survival, long term follow-up is needed. We continue to collect data of this study population in a prospective database.

To conclude, the sensitivity of three-modality breast cancer screening in *BRCA1/2* mutation carriers after RRSO is lower than breast cancer screening before RRSO. It is the lower sensitivity of MRI that contributed largely to the lower sensitivity of the total screening program, while mammography sensitivity increases after RRSO. In our post RRSO population, CBE did not contribute to tumour detection. Our findings suggest that intensive breast cancer screening with both MRI and mammography should be continued in *BRCA1/2* mutation carriers, after RRSO.
