Anti-neutrophil cytoplasmic antibodies (ANCAs), such as those directed towards proteinase 3 (PR3) and myeloperoxidase (MPO), are associated with a distinct form of small-vessel vasculitis, known as ANCA-associated vasculitis (AAV), a term that encompasses granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). Screening for the presence of ANCAs is a commonly used diagnostic test for AAV. According to an international consensus statement issued in 1999 (REF. 1), indirect immunofluorescence (IIF) should be used to screen for ANCAs, and samples containing ANCAs should then be tested by immunoassays for proteinase 3 (PR3)-ANCAs and myeloperoxidase (MPO)-ANCAs. The distinction between PR3-ANCAs and MPO-ANCAs has important clinical and pathogenic implications. As dependable immunoassays for PR3-ANCAs and MPO-ANCAs have become broadly available, there is increasing international agreement that high-quality immunoassays are the preferred screening method for the diagnosis of ANCA-associated vasculitis. The present Consensus Statement proposes that high-quality immunoassays can be used as the primary screening method for patients suspected of having the ANCA-associated vasculitides GPA and MPA without the categorical need for IIF, and presents and discusses evidence to support this recommendation.

Anti-neutrophil cytoplasmic antibodies (ANCAs), such as those directed towards proteinase 3 (PR3) and myeloperoxidase (MPO), are associated with a distinct form of small-vessel vasculitis, known as ANCA-associated vasculitis (AAV), a term that encompasses granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). Screening for the presence of ANCAs is a commonly used diagnostic test for AAV. According to an international consensus statement issued in 1999 (REF. 1), indirect immunofluorescence (IIF) should be used as the initial screening method to detect the presence of ANCAs. Samples that test positive by IIF should then be tested by immunoassays to detect ANCAs specific for PR3 and MPO. Although this testing algorithm is still widely applied, the position of IIF is being questioned.

Over the past 15 years, the performance of enzyme-linked immunosorbent assays (ELISAs) have improved and novel, sensitive and automated technologies, such as fluoroenzyme immunoassays, chemiluminescence assays and multiplexed flow immunoassays, have been introduced. Additionally, assay setup (antigen presentation) has advanced with the development of second generation (capture-based) and third generation (anchor-based) assays. In general, currently available assays for PR3-ANCAs and MPO-ANCAs are highly sensitive and specific for diagnosing GPA and MPA (reviewed elsewhere).

The availability of reliable antigen-specific immunoassays has raised doubts as to whether the two-stage diagnostic strategy currently recommended for ANCA detection is the best approach. The use of antigen-specific assays as the initial and/or only step has been suggested as an alternative approach to screening by IIF (REFS 4, 5). In a 2016 large multicentre study by the European Vasculitis Study Group (EUVAS), the diagnostic performance of antigen-specific immunoassays was confirmed to equal or even to exceed the diagnostic performance of IIF (REF. 6).

Abstract | Anti-neutrophil cytoplasmic antibodies (ANCAs) are valuable laboratory markers used for the diagnosis of well-defined types of small-vessel vasculitis, including granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). According to the 1999 international consensus on ANCA testing, indirect immunofluorescence (IIF) should be used to screen for ANCAs, and samples containing ANCAs should then be tested by immunoassays for proteinase 3 (PR3)-ANCAs and myeloperoxidase (MPO)-ANCAs. The distinction between PR3-ANCAs and MPO-ANCAs has important clinical and pathogenic implications. As dependable immunoassays for PR3-ANCAs and MPO-ANCAs have become broadly available, there is increasing international agreement that high-quality immunoassays are the preferred screening method for the diagnosis of ANCA-associated vasculitis. The present Consensus Statement proposes that high-quality immunoassays can be used as the primary screening method for patients suspected of having the ANCA-associated vasculitides GPA and MPA without the categorical need for IIF, and presents and discusses evidence to support this recommendation.

Given the improvements in antigen-specific immunoassays, the international consensus on the testing of ANCAs in small-vessel vasculitis seems in need of updating. In this manuscript, a revised 2017 international consensus is proposed by a group of international experts (from North and Central America, Australia, Europe and Asia) in the ANCA field. This Consensus Statement highlights the value of ANCA testing as a tool for diagnosis (but not follow-up) of GPA and MPA and gives a historical perspective of ANCAs in small-vessel vasculitis. This Consensus Statement does not, however, present evidence-based guidelines or a meta-analysis.

Methods

This Consensus Statement was prepared by a group of experts from four European laboratories (X.B., J.D., N.R., J.W.C.T. and E.C.) in person and by correspondence. The draft was circulated to each contributor and modified, and the resulting document was distributed by e-mail to 16 experts from four continents, selected based on their expertise and knowledge in clinical and/or laboratory aspects of AAV. This revised document resulted in a second round of discussions and revisions. The final document was returned to all contributors for ratification.

The Consensus Statement is based on the results of a multicentre European Vasculitis Study Group (EUVAS) evaluation of the value of IIF versus antigen-specific immunoassays for ANCA detection. This study, which showed a large variability between different IIF methods and a good diagnostic performance of PR3-ANCA and MPO-ANCA immunoassays, indicated that the 1999 international consensus on ANCA testing for AAV needed revision. When the consensus was put together, the topics that were discussed encompassed IIF versus immunoassays for ANCA detection in GPA and MPA, diagnostic strategies, clinical indications for ANCA testing, value-added reporting of ANCA test results and ANCAs in conditions other than GPA and MPA.

Historical perspective

First discoveries in ANCA detection. The history of ANCAs in AAV is depicted in FIG. 1 and has been previously described elsewhere. Although ANCAs were initially discovered in 1959 in patients with chronic inflammatory disorders, the association between vasculitis (in particular glomerulonephritis) and autoantibodies reacting with cytoplasmic components of neutrophils only became apparent in 1982 (REF. 16). In 1985, van der Woude et al. detected such anti-cytoplasmic antibodies by IIF in a mixed Dutch–Danish cohort of patients with GPA, noting that these antibodies produced a cytoplasmic staining pattern (C-ANCA). Following description of C-ANCA, autoantibodies that produce a perinuclear staining pattern (P-ANCA) by IIF were also reported in patients with systemic arteritis and glomerulonephritis, the relevant autoantigens for C-ANCA and P-ANCA were identified as PR3 and MPO, respectively.

ANCAs have subsequently been associated with other small-vessel vasculitides, including MPA, eosinophilic granulomatosis with polyangiitis (EGPA) and idiopathic necrotizing crescentic glomerulonephritis. At first, ‘in-house’ ELISAs were used for the detection of MPO-ANCAs and PR3-ANCAs. However, following a recognized need for standardization, international efforts were undertaken to develop and standardize solid-phase ANCA assays (discussed below). In 1998, 15 clinical centres evaluated such standardized assays for the detection of ANCA in patients with idiopathic systemic vasculitis (TABLE 1), concluding that the diagnostic value of ANCA detection by IIF could be greatly enhanced by combining this test with an antigen-specific ELISA. In this study, Hagen et al. showed that ANCA detection by IIF was sensitive for GPA, MPA and renal-limited vasculitis (sensitivities of 81–85%) but had a low specificity (76%). Combining IIF with an ELISA (PR3-ANCA and MPO-ANCA) increased the specificity to 98% and decreased the sensitivities to 67–82%.

At the multicentre study were the basis of the 1999 international consensus statement on the testing and reporting of ANCAs. This 1999 consensus statement states that...
ANCAs are best demonstrated by using a combination of IIF and immunoassay (PR3-ANCA or MPO-ANCA) and that IIF must be performed on all serum samples of patients suspected of having AAV. Serum samples containing ANCA by IIF should then be tested for PR3-ANCA and MPO-ANCA. The testing algorithm proposed by this consensus was validated in 2002 in a meta-analysis study, leading to the conclusion that combining results obtained by IIF and ELISA (combining either C-ANCA and PR3-ANCA or P-ANCA and MPO-ANCA findings) optimizes the diagnostic performance of ANCA testing for AAV.

**Incorporation of ANCA tests in clinical decisions.** In the early 1990s, classification criteria and nomenclature for the small-vessel vasculitides were assigned by the American College of Rheumatology and the Chapel Hill Consensus Conference (CHCC), respectively. These criteria were based on clinical manifestations and hallmark pathological features of tissue biopsy samples, but did not incorporate ANCA testing. Small-vessel vasculitides were originally considered to be only ANCA-associated, but subsequent animal model studies showed that ANCA also have pathogenic potential, which was clearly demonstrated for MPO-ANCA in 2002 and later indirectly for PR3-ANCA. The fact that different approaches were needed to demonstrate the pathogenic role of MPO-ANCA and PR3-ANCA in these studies increased the awareness that instead of distinguishing between patients with GPA, MPA, and EGPA, differentiating between patients with MPO-ANCA and PR3-ANCA might be more clinically relevant. This notion was underscored in 2012 by the finding that autoantibodies can be used to differentiate between genetically distinct subsets of patients with AAV. The combined potential pathogenic role of these autoantibodies, and the good test performances of the ANCA-assays, formed the basis for incorporating ANCA into nomenclature criteria; in the 2012 CHCC update on the nomenclature of the vasculitides, AAV was included as a category of vasculitides. Importantly, CHCC is a nomenclature system, not a classification system or a diagnostic system, and at present there are no validated diagnostic criteria for AAV. ANCA detection was included as part of this consensus methodology developed in 2007 for the classification of AAV and polyarteritis nodosa in epidemiological studies, and EULAR have pointed to considering ANCA in diagnostic and classification criteria for systemic vasculitis.

**Novel technical developments in ANCA detection.** Since the description of the first commercial ANCA ELISA in 1990, an increasing number of commercial ANCA assays have become available. ELISAs have evolved in the way in which antigens are coupled to the carrier: from direct antigen binding (first generation ELISA) to capture-based antigen binding (second generation ELISA) and anchor-based antigen binding (third generation ELISA). Similarly, IIF has also undergone technical innovations: neutrophil substrates have been combined with antigen-specific...

This table compares the specificity and sensitivity of indirect immunofluorescence (IIF) and antigen-specific immunoassays for newly diagnosed patients with granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA) as reported by Hagen et al. (the basis for the 1999 consensus) and Damoiseaux et al. (the basis for the revised 2017 consensus). Hagen et al. used one IIF method, three different proteinase 3 (PR3)-anti-neutrophil cytoplasmic antibody (ANCA) enzyme-linked immunosorbent assays (ELISAs) and one myeloperoxidase (MPO)-ANCA ELISA, whereas Damoiseaux et al. performed IIF using two methods at two different sites and eight different PR3-ANCA and eight different MPO-ANCA antigen-specific enzyme immunoassays. AAV, ANCA-associated vasculitis; C-ANCA, cytoplasmic ANCA staining pattern; P-ANCA, perinuclear ANCA staining pattern.

### Harmonization and standardization of ANCA testing

A standard procedure for ANCA IIF was released in 1988 [REF 51, 52], prescribing the use of a mixture of neutrophils and other white blood cells smeared on glass slides and fixed with ethanol to differentiate between C-ANCA and P-ANCA, and to determine the ANCA titre of a sample. The result is considered ‘not determinable’ if the serum contains antinuclear antibodies (ANAs), as detected on human epithelial type 2 (HeP-2) cells, at a similar titre to that determined for P-ANCA. At present, most clinical laboratories use commercial cell substrates for ANCA detection by IIF and, in many cases, neutrophils are used on their own rather than in a mixture with other cells.

Efforts in harmonizing ANCA detection began in 1993 with an international study on the standardization of ANCA assays [21]. In this multicentre study, the value of IIF and solid-phase techniques (ELISAs) for ANCA detection was evaluated [22]. The IIF test results across different centres were comparable for sera containing high ANCA titres (even when different methods were used), whereas the results indicated that the ELISAs for PR3-ANCAs were not well-standardized, except when purified PR3 was used as the antigen preparation [23]. For the MPO ELISAs, various antigen preparations revealed only minor discrepancies in results, with the researchers concluding that all of these MPO preparations could be used in ELISAs for the detection of MPO-ANCAs [24].

An addendum to the 1999 international consensus was released in 2003 recommending the use of internal and external quality control procedures in ANCA testing [53]. In 2007, the first human reference sera for MPO-ANCAs and PR3-ANCAs became available via the Centers for Disease Control and Prevention (CDC). These samples were prepared under the auspices of the International Union of Immunological Societies (IUIS). Each reference preparation was obtained by plasmapheresis from a single donor and was confirmed to be monospecific for either MPO or PR3. To our knowledge, at least four companies currently calibrate their ANCA assays against the IUIS-CDC reference sera: the second generation ANCA ELISAs of Wieslab (Euro-Diagnostica), a third generation ANCA FEIA (Thermo-Fisher), a cyto bead IIF assay (Medipan) and a CLIA (Inova). In 2016, the Institute for Reference Materials and Measurements (IRMM) released certified reference material for MPO-ANCAs (ERM-DA476/IFCC) [54]. This reference material is based on a plasmapheresis sample from a single patient with vasculitis. A similar approach for developing certified reference material for PR3-ANCAs is currently in progress [54]. Although the use of a certified reference material will reduce variability between ANCA results obtained with different assays, it should be noted that autoantibodies are not a uniform analyte. This caveat holds true for patient sera, as well as for the reference antibody preparations. Antibodies differ in terms of their IgG subclass composition as well as the avidity, glycosylation and epitope specificity of the antibodies [55–57]. In particular, epitope specificity might affect standardization of different assay formats, as the accessibility of epitopes might differ between different assay formats. Therefore, the feasibility of using reference antibody preparations for standardization of autoantibody assays (that is, MPO-ANCA and PR3-ANCA assays) remains to be established [12].
**Rationale for a new consensus**

In a 2016 multicentre EUVAS evaluation, the performance of manual and automated IIF was compared with the performance of various antigen-specific immunoassays for ANCA detection. Four European centres contributed samples and clinical data from newly diagnosed patients with GPA (n = 186) and MPA (n = 65) and relevant disease controls (n = 924). Because ANCA levels might change during treatment, only newly diagnosed patients were included. Eight different antigen-specific immunoassays (from seven manufacturers, encompassing different technological platforms) and four different IIF assays (including two automated assays) were evaluated. As illustrated in Fig. 2, the results of the study revealed a large amount of variability between IIF methods. Moreover, the pattern assignment between IIF methods also varied. By contrast, immunoassays for PR3-ANCA and MPO-ANCA had a high diagnostic performance. This study, which was performed on diagnostic samples obtained from patients who had not received any immunosuppressive treatment, did not reveal consistent differences between different assay generations and formats. Hence, in contrast to expectations, the improvements in test characteristics were independent of the assay principle. Notably, some patients tested negatively by both IIF and immunoassay, or by either immunoassay or IIF. Depending on the assay, 11–17% of patients with AAV were negative by IIF and 9–16% by immunoassay. Hence, antigen-specific immunoassays might detect antibodies that are missed by IIF and vice versa.

When compared with the assays used by Hagen et al., the antigen-specific immunoassays used in the EUVAS study performed much better, with a higher specificity, demonstrating the marked improvements that have been made to these assays (Table 1). Of note, however, the composition of the control groups differed between the two studies. For example, Hagen et al. included patients with inflammatory bowel disease (IBD), whereas Damoiseaux et al. did not, using instead relevant disease controls for AAV (that is, patients for whom the clinician considered the possibility of AAV and requested ANCA testing, but for whom AAV was eventually excluded), as well as cohorts of patients with a systemic rheumatic disease.

Given the large variability between IIF methods and poor performance of some IIF methods (manual as well as automated), in addition to the good performance of the immunoassays evaluated, the authors of the EUVAS study concluded that screening with IIF and follow-up testing with antigen-specific immunoassay was not necessary for maximal diagnostic accuracy. These results indicated that the 1999 international consensus on ANCA testing for AAV needed revision.

**New recommendations**

In this Consensus Statement, we recommend the use of high-quality immunoassays as the preferred first screening method for GPA and MPA, and put forward a new testing algorithm (recommendations 1–6). These recommendations are visually represented in Fig. 5 and displayed in Box 1.

To determine if ANCA testing is advisable, adherence to a strict gating strategy, based on clinical manifestations defined in the 1999 consensus (Box 2), is recommended. This strategy strongly reduces the number of ANCA test requests and improves the diagnostic performance of ANCA testing, with fewer false positive results (recommendation 1).

Based on the results of this consensus initiative, there is substantial international agreement that high-quality antigen-specific immunoassays are the preferred screening methodology for the diagnosis of AAV (recommendation 2). IIF is no longer deemed suitable as the first screening test, and adds little additional benefit to antigen-specific assays in the diagnosis of AAV when the pre-test probability for the disease is high.
Single immunoassays never have a sensitivity and specificity of 100%. In patients where there is a high degree of clinical suspicion and negative ANCA test results, testing by another method can be useful to increase sensitivity (recommendation 3). False-positive results do occur with immunoassays, mainly in samples with a low degree of positivity. Therefore, performing a second assay or IIF can marginally increase the specificity in cases of low-positive test results. When new assays are introduced (including assays not included in the EUVAS study), the diagnostic performance of such assays should be checked based on samples from patients with GPA or MPA and relevant disease controls.

A diagnosis of AAV cannot be excluded for ANCA-negative patients (recommendation 4) and biopsies of the affected organs should be performed in seronegative patients. Although ANCAs are helpful in the diagnosis of AAV, the diagnosis of AAV should be based on clinical-pathological features (recommendation 5).

Interpretation of test results can be improved by the application of appropriately designed reference ranges (and test result intervals) for antibody levels (recommendation 6). The concept of test result interval-specific likelihood ratios is explained in the next section.

The specific role of IIF testing in ANCA testing algorithms should be determined individually by diagnostic laboratories on the basis of the specific clinical need and circumstances of the laboratory. If a laboratory prefers to use IIF as a screening assay in locally determined best-testing algorithms, then the laboratory needs to ensure that the IIF operates at a high level of sensitivity, as the performance of IIF varies greatly between laboratories.

Improving clinical interpretations
As immunoassays are expected to be increasingly used to screen for AAV, retrieving the maximum amount of clinically useful information from PR3-ANCA and MPO-ANCA test results is important. Traditionally, a single cut-off value is employed to predict clinically-relevant reactivity. However, a lot of information is lost when only binary results (positive or negative) are considered, whereas the likelihood for AAV increases with increasing levels of PR3-ANCAs and MPO-ANCAs.

The likelihood ratio helps to describe the clinical value of a test result. This ratio can be defined for different test result intervals of an assay and is independent of the disease prevalence and pre-test probability. A likelihood ratio of 1 indicates no difference in pre-test to post-test probability, whereas likelihood ratios of >10 or <0.1 indicate large, often clinically important differences in pre-test to post-test probability.

A detailed analysis of the large dataset from the multinational EUVAS study exemplified and confirmed that the likelihood ratio for AAV increases with increasing levels of PR3-ANCAs and MPO-ANCAs. For example, the likelihood ratio for AAV was calculated to be 0.1, 1.2, 10.2, 64.6, and ∞ for test result intervals of 0–12 CU, 12–24 CU, 24–78 CU, 78–1,050 CU, and 1,050–3,500 CU, respectively, when using the PR3-ANCA and MPO-ANCA QuantaFlash CLIA (Inova).

Knowledge of test result-specific likelihood ratios can help clinicians and laboratory professionals to better interpret results. Having the likelihood ratios enables the calculation of the post-test probability for a disease
The following new international recommendations should be considered for anti-neutrophil cytoplasmic antibody (ANCA) detection in the small-vessel vasculitides granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA):

**Recommendation 1**
A gating policy for requesting an ANCA test is advisable and adherence to clinical guidelines for ANCA testing (BOX 2) is recommended.

**Recommendation 2**
High-quality antigen-specific assays for proteinase 3 (PR3)-ANCAs and myeloperoxidase (MPO)-ANCAs should be used as the primary screening method for ANCA.

**Recommendation 3**
If results for both PR3-ANCAs and MPO-ANCAs are negative, and there is still a strong suspicion of small-vessel vasculitis, then use of other immunoassays and/or indirect immunofluorescence (IIF), or referral to an experienced laboratory is recommended. Performing a second assay or IIF can also marginally increase the specificity in cases of low-positive test results.

**Recommendation 4**
A diagnosis of ANCA-associated vasculitis (AAV) cannot be excluded on the basis of negative PR3-ANCA and MPO-ANCA results.

**Recommendation 5**
A positive PR3-ANCA and/or MPO-ANCA result only contributes to the diagnostic work-up for AAV and is not diagnostic by itself.

**Recommendation 6**
Taking into account antibody levels improves clinical interpretation.

---

**Box 1 | Recommendations for ANCA testing**

The conversion of probability to odds is carried out using the equation odds = probability/(1 − probability). The conversion of probability to odds is carried out using the equation odds = probability/(1 − probability).

**Box 2 | Clinical indications for ANCA testing**

In order to assure appropriate anti-neutrophil cytoplasmic antibody (ANCA)-test usage to support the diagnosis of ANCA-associated vasculitis (AAV), ANCA should be requested for patients with the following clinical indications:

- Glomerulonephritis, especially rapidly progressive glomerulonephritis
- Pulmonary haemorrhage, especially pulmonary renal syndrome
- Cutaneous vasculitis with systemic features
- Multiple lung nodules
- Chronic destructive disease of the upper airways
- Long-standing sinusitis or otitis
- Subglottic tracheal stenoses
- Mononeuritis multiplex or other peripheral neuropathy
- Retro-orbital mass
- Scleritis

---

**ANCs in other small-vessel vasculitides.** ANCs are also found in 30–38% of patients with EGPA, a disease characterized by asthma, eosinophilia and granulomatous inflammation, and in 20–35% of patients with anti-glomerular basement membrane (anti-GBM) disease. The majority of these ANCA-positive patients have MPO-ANCA. As the phenotypes of patients with EGPA are heterogeneous, EGPA was not included in this Consensus Statement.

**ANCAs in gastrointestinal disorders.** In addition to vasculitis, ANCs are found in patients with gastrointestinal disorders such as IBD, primary sclerosing cholangitis and inflammatory liver diseases (such as autoimmune hepatitis, primary biliary cirrhosis and chronic viral hepatitis). These diseases are associated with a slightly aberrant P-ANCA pattern that is often referred to as atypical P-ANCA or X-ANCA.

In gastrointestinal disorders, P-ANCA is mainly observed in patients with ulcerative colitis (50–67%), but is also seen in patients with Crohn’s disease (6–15%), and to a lesser extent in disease controls (<11%). Combining P-ANCA with anti-Saccharomyces cerevisiae antibody (ASCA) measurements might improve the clinical utility of this marker. ASCAs are found in 40–60% of patients with Crohn’s disease, 4–14% of patients with ulcerative colitis and <5% of controls. The combination of an ASCA-positive and P-ANCA-negative test result is associated with Crohn’s disease, whereas the combination of an ASCA-negative and P-ANCA-positive test result is associated with ulcerative colitis. However, the clinical usefulness of ANCs in IBD has been questioned. Given the limited sensitivity of ANCA detection in ulcerative colitis, a European evidence-based consensus on the diagnosis and management of ulcerative colitis concluded that routine use of ANCA detection for diagnosis and therapeutic decisions was not clinically justified.

In the past few years, studies have also reported that sensitive immunoassays can detect PR3-ANCAs in patients with ulcerative colitis and primary sclerosing cholangitis.

<tr>
<td>The conversion of probability to odds is carried out using the equation odds = probability/(1 − probability).</td>
</tr>
</tbody>
</table>

When the pre-test probability is known using the formula: post-test odds = pre-test odds × likelihood ratio, FIGURE 4 illustrates the post-test probability for AAV as a function of the pre-test probability (using the formula mentioned above) for different test result intervals. Such graphical representation is a better way to help the interpretation of a test result than describing the sensitivity and specificity of an assay and enables the post-test probability to be estimated from the assay test result without the need for a calculation. However, an estimate of the pre-test probability is first required; the pre-test probabilities for AAV associated with particular clinical presentations can be obtained from the literature and have been previously summarized. For instance, the pre-test probability for AAV in adult patients presenting with haematuria, proteinuria and creatinine levels of 1.5–3 mg/dL is 7%.

If ANCA testing reveals a test result with a likelihood ratio of 60 (for example, a test result between 78–1,050 CU by QuantaFlash), then the post-test probability for AAV will be 82%. By contrast, the post-test probability of a test result with a likelihood ratio of 10.2 or 0.1 will be, respectively, 47% and 0.7%. Such knowledge might add value to a specific test result and help in the clinical interpretation of the result.
Our consensus recommendations are applicable to AAV, but not to gastrointestinal disorders. As ANCA can be found in gastrointestinal disorders, we advise differentiating between requesting ANCA tests in the context of AAV and in the context of gastrointestinal disorders (Fig. 3). The coexistence of AAV with IBD has been described in some patients, but is rare\(^{25,96}\). In this context, IBD usually precedes AAV by several years\(^{96}\).

ANCAs in systemic inflammatory and malignant diseases. ANCAs have also been reported in systemic diseases such as rheumatoid arthritis and systemic lupus erythematosus (reviewed elsewhere\(^{97}\)). A rare association of AAV with malignant haemopathy (mainly non-Hodgkin lymphoma and myelodysplasia) has additionally been described\(^{89}\).

ANCAs and infection. Evidence suggests that infections have a central role in the formation of ANCAs and that chronic infections mimic AAV\(^{97}\); infective endocarditis can mimic ANCA-associated glomerulonephritis and patients with infective endocarditis can develop ANCAs. Langlois et al.\(^{100}\) reported ANCAs by IIF in 12 out of 50 patients (24%) with infective endocarditis; four patients had PR3-ANCAs, one patient had MPO-ANCAs and two patients had both PR3-ANCAs and MPO-ANCAs. Mahr et al.\(^{101}\) reported ANCA by IIF in 20 out of 109 patients (18%) with infective endocarditis (14 patients were positive for C-ANCA and six were positive for P-ANCA); of these, three patients had C-ANCA and PR3-ANCAs, two patients had C-ANCA and MPO-ANCAs, one patient had P-ANCA and MPO-ANCAs, one patient had just PR3-ANCAs and one patient had just MPO-ANCAs. Misdiagnosis of sub-acute bacterial endocarditis as AAV and initiation of inappropriate immunosuppressive therapy can have devastating consequences\(^{102}\). Thus, infections such as infective endocarditis, hepatitis C infection and tuberculosis should be excluded before establishing a diagnosis of AAV and starting immunosuppressive therapy. The EUVAS multicentre study was performed in Europe, where the prevalence of infections such as malaria, leprosy and tuberculosis is low compared with regions such as India or Mexico, where positive ANCA results have been reported in patients with such infections\(^{103,104}\). Controversy still exists over ANCA positivity in patients with tuberculosis\(^{103-105}\).

Drug-induced AAV. Levamisole-adulterated cocaine and drugs such as hydralazine, propylthiouracil and minocycline can cause secondary forms of AAV (reviewed elsewhere\(^{106,107}\)). Vasculitis, MPO-ANCAs, PR3-ANCAs, human neutrophil elastase (HNE)-ANCAs and ANAs can all be found in patients with levamisole-adulterated cocaine-induced AAV\(^{107}\).

In a series of 30 patients with AAV associated with cocaine use, all patients had MPO-ANCA and 50% had PR3-ANCAs\(^{108}\); double positivity for MPO-ANCAs and PR3-ANCAs is a characteristic of this disease\(^{108}\). In patients with hydralazine-induced AAV, MPO-ANCAs can be found together with HNE-ANCAs, lactofernin-ANCAs and ANAs\(^{97}\). In patients with propylthiouracil-mediated AAV, high titres of MPO-ANCAs are usually found\(^{107}\). Of note, a substantial fraction (32–41%) of propylthiouracil-treated patients develop ANCA (PR3-ANCAs and HNE-ANCAs) without symptoms\(^{106,109}\). In minocycline-induced AAV, P-ANCA is frequently found (~80% of individuals) with antibody reactivity against either MPO, HNE, bactericidal permeability increasing protein (BPI), lactofernin or cathepsin G\(^{110-113}\). Patients are also frequently positive for ANAs.

Taken together, most patients with drug-induced AAV have MPO-ANCA, which can be found in combination with antibodies to other neutrophil cytoplasmic proteins and ANAs.

Conclusion

In the past 25 years, PR3-ANCA and MPO-ANCA assays have evolved from home-made assays (using crude extracts) that have low levels of specificity, to commercially available assays with improved sensitivity and specificity that can be run on automated platforms.
A 2016 multicentre EUVAS evaluation demonstrated the good diagnostic performance of current antigen-specific immunoassays for ANCA detection in patients with GPA and MPA, and the high variability in performance of IIF. Our recommendation is that high-quality immunoassays for PR3-ANCA and MPO-ANCA are the preferred methods for the diagnostic evaluation of patients with AAV, without the categorical need for IIF. This consensus recommendation applies to ANCA testing for the diagnosis of vasculitis, in particular GPA and MPA, but does not apply to ANCA testing as an adjunct for the diagnosis of IBD, autoimmune hepatitis or drug-induced autoimmunity. In certain settings, infections should be ruled out and a detailed history of medications and illicit drug use should be retrieved. Clinical interpretation of ANCA test results can be improved by taking into account antibody levels and applying test result interval specific likelihood ratios. These recommendations aim to help in the diagnosis of GPA and MPA, and in the standardization of ANA detection and interpretation. The performance of this consensus recommendation should be evaluated regularly.
