Skin accumulation of advanced glycation end products is increased in patients with an abdominal aortic aneurysm

Jeltje Boersema, BSc, Lisanne C. de Vos, MD, PhD, Thera P. Links, MD, PhD, Douwe J. Mulder, MD, PhD, Andries J. Smit, MD, PhD, Clark J. Zeebregts, MD, PhD, and Joop D. Lefrandt, MD, PhD, Groningen, The Netherlands

ABSTRACT

Objective: Advanced glycation end products (AGEs) are implicated in the pathogenesis of cardiovascular disease. Accumulation of AGEs is driven by oxidative or glycemic stress and can be assessed by skin autofluorescence (SAF). SAF is increased in patients with peripheral artery disease (PAD) and independently associated with mortality and major adverse cardiovascular events in these patients. PAD and abdominal aortic aneurysm (AAA) share several risk factors. Inflammation is an important process in AAA formation and increases levels of oxidative stress. We therefore hypothesized that SAF would be increased in AAA patients compared with controls.

Methods: A case-control study was performed in 248 AAA patients and 124 controls without AAA or PAD matched for age and presence of diabetes mellitus. SAF was noninvasively assessed with the AGE Reader (Diagnoptics Technologies BV, Groningen, The Netherlands).

Results: SAF was higher in AAA patients than in controls: 2.89 ± 0.63 vs 2.68 ± 0.63 arbitrary units (P = .003). PAD comorbidity was associated with increased SAF within the AAA patient group (P = .01). After correction for known factors influencing SAF (age, current smoking, hypertension, and estimated glomerular filtration rate), PAD comorbidity remained an independent determinant of SAF. Logistic regression analysis of the total cohort showed an unadjusted odds ratio (OR) of 1.74 (95% confidence interval [CI], 1.20-2.51) for the presence of AAA with each unit increase of SAF and an adjusted OR of 1.78 (95% CI, 1.22-2.60) after correction for cardiovascular comorbidity (cerebrovascular disease and coronary artery disease). After additional correction for sex, current smoking, hypertension, and use of lipid-lowering drugs, this significance was lost (adjusted OR, 1.53; 95% CI, 0.94-2.48).

Conclusions: Skin accumulation of AGEs, measured by SAF, is increased in patients with AAA compared with controls without AAA or PAD, independent of the presence of coronary artery disease and cerebrovascular disease. In AAA patients, SAF is closely associated with the presence of PAD and cardiovascular risk factors.

An abdominal aortic aneurysm (AAA) is characterized by enlargement of the aorta as a consequence of pathophysiological changes in the aortic vascular wall, including inflammation, smooth muscle cell apoptosis, and proteolysis of elastin and collagen in the tunica media. Most AAAs are discovered as an incidental finding because this disease is asymptomatic in most patients. Rupture of the AAA is generally an emergency situation with an estimated mortality rate of 80%. Advanced glycation end products (AGEs) are formed by nonenzymatic reactions on reducing sugars and proteins and have two potentially harmful effects. First, formation of cross-links contributes to stiffening of the myocardium and arteries. Second, interaction with the receptor for AGEs induces inflammatory responses through activation of nuclear factor-κB and consecutive release of proinflammatory cytokines.

Assessment of skin AGEs can be performed with a noninvasive technique called skin autofluorescence (SAF). The estimated turnover time of skin collagen is 15 years; thus, skin AGEs and SAF represent a long-term metabolic memory. In addition, SAF is positively related to AGE levels in cardiac tissue and venous bypass graft material, both vascular tissues with also a typical slow turnover.

Although the formation and accumulation of AGEs in long-lived tissues occurs physiologically with aging, this formation is enhanced in conditions associated with hyperglycemia or oxidative stress such as diabetes mellitus (DM), autoimmune disease, renal insufficiency, and atherosclerosis. As a result, SAF is increased in patients with these conditions compared with controls, and increased SAF is also associated with major adverse
cardiovascular events in patients with DM, myocardial infarction, and peripheral artery disease (PAD).16–17

PAD and AAA disease share several risk factors and are frequently found in the same patient. Inflammation is an important pathway of AAA formation, mediating elastin and collagen degradation by proteases derived from inflammatory cells.18 This led us to hypothesize that SAF, as a measure of skin AGEs, would be increased in patients with an AAA; therefore, the aim of this study was to compare SAF levels in AAA patients and controls. We also investigated whether SAF is associated with the presence of AAA after correction for cardiovascular risk factors, such as smoking, and cardiovascular comorbidity, expressed by a history of cerebrovascular disease (CVD) or coronary artery disease (CAD).

METHODS

Study population. We performed a case-control study. AAA patients were recruited from the vascular surgery outpatient clinic at the University Medical Center Groningen (UMCG), The Netherlands, between 2007 and 2011. Patients at least 18 years of age with a confirmed AAA were eligible to participate. AAA was ascertained by evidence of an enlarged diameter of the aorta of ≥30 mm on ultrasound imaging, magnetic resonance angiography, or computed tomography angiography. In case of an emergency or elective repair without available medical imaging reports, sur-
gical reports or referral letters were used to confirm the diagnosis.

AAA patients and controls were matched 2:1 by age and presence of DM (Fig 1). Controls were selected from earlier studies. Diabetic controls were selected from a cohort (n = 973) from the diabetes outpatient clinic, Zwolle, The Netherlands.11 The nondiabetic control group consisted of patients admitted to the UMCG for surgical interventions (n = 231) unrelated to cardiovascular disease and of patients who visited the vascular surgery outpatient clinic in the UMCG (n = 121), mostly because of varicose veins or carotid artery stenosis, who had no history of symptoms of AAA or PAD.12,13

Exclusion criteria for AAA patients and controls were sepsis, recent myocardial infarction or stroke, defined as an event ≤3 months before recruitment, renal replace-
ment therapy or end-stage renal disease (estimated glomerular filtration rate [eGFR] <15 mL/min/1.73m²), solid organ transplantation, or active cancer. AAA patients with a mycotic or inflammatory aneurysm or a history of connective tissue disease were excluded. Control patients with a history or symptoms of AAA or PAD were also excluded.

All participating patients gave informed consent. The study was approved by the local Institutional Review Board and complied with the principles of the Declara-
tion of Helsinki.

ARTICLE HIGHLIGHTS

- **Type of Research:** Single-center prospective case-controlled study

- **Take Home Message:** Skin accumulation of advanced glycation end products as measured by skin autofluorescence was increased in 248 patients with abdominal aortic aneurysm compared with 124 matched controls.

- **Recommendation:** This study suggests that using skin autofluorescence to measure advanced glycation end products may be a useful in the detection of patients with abdominal aortic aneurysm.

Data collection. Traditional cardiovascular risk factors were prospectively assessed, including current smoking status, body mass index, presence of DM, hypertension, eGFR, and use of lipid-lowering, glucose-lowering, or anticoagulant drugs. eGFR was calculated from the serum creatinine level using the Modification of Diet in Renal Disease formula.19 Hypertension was defined as a systolic blood pressure ≥140 mm Hg, a diastolic blood pressure ≥90 mm Hg, or the use of blood pressure-lowering drugs. Lipid-lowering therapy was defined as the use of statins, ezetimibe, or fibrates. For glucose-lowering therapy, the use of metformin, dipeptidyl peptidase 4 inhibitors, repaglinide, sulfonylurea der-

atives, pioglitazone, glucagon-like peptide 1 receptor agonists, sodium-glucose cotransporter 2 inhibitors, and insulin was assessed. Anticoagulant therapy was defined as the use of anticoagulant or antiplatelet therapy.

History of cardiovascular comorbidity was retrieved from medical records and divided into CAD, CVD, and PAD. CAD was defined as a history of angina pectoris, myocardial infarction, percutaneous coronary intervention, or coronary artery bypass graft. CVD was defined as a history of stroke, transient ischemic attack, carotid endarterectomy, or carotid stenting. PAD was defined as a resting ankle-brachial index ≤0.90 combined with confirmation of obstructive disease on computed tomography angiography, magnetic resonance angiography, catheter angiography, or duplex ultrasound imaging.

For AAA patients, data on the diameter, surgical repair, and rupture of the aneurysm were obtained. The presence of aneurysms in other locations in addition to the abdominal aorta was assessed. Rupture of the AAA was confirmed using ultrasound imaging or during surgical repair of the aneurysm.

SAF assessment. SAF as a noninvasive measure of skin AGEs was assessed using the AGE Reader (Diagnoptics Technologies BV, Groningen, The Netherlands). This de-
vice uses ultraviolet A light to measure the dermal con-
tent of certain AGEs using their fluorescent properties.
An area of 4 cm² on the inner forearm is shielded from surrounding light and exposed to excitation light with a wavelength between 300 and 420 nm with a peak of 370 nm. Fluorescent AGEs characteristically emit light of a wavelength between 420 and 600 nm with a peak of ~440 to 450 nm, whereas reflected light is identical to the excitation light. SAF is calculated as the ratio between emission light and reflected light, multiplied by 100 and expressed in arbitrary units. Previous studies by Meerwaldt et al showed a strong correlation between SAF and skin biopsy specimen content of several important AGEs, including the fluorescent AGE pentosidine and two nonfluorescent AGEs, N-carboxy-methyl-lysine and N-carboxy-ethyl-lysine. The inner forearm was accepted as the standard and most accessible location to measure SAF because a validation study showed a strong correlation between measurements of the arm and the leg. The mean SAF is calculated from three consecutive measurements performed automatically by the AGE Reader. An intraindividual variance of 4.5% was shown in an earlier study with measurements performed on a single day.

Statistical analysis. Data are shown as mean ± standard deviation, median (interquartile range [IQR]), or as number (%). Characteristics of AAA patients and controls were compared using the Student independent t-test or the χ² test. SAF between groups was compared using the Student independent t-test.

The determinants of SAF in the AAA patients were evaluated in a backward multivariable linear regression analysis. A P value of <.05 was considered statistically significant. To study the association between SAF and the presence of AAA, a logistic regression analysis was performed in the complete study group (AAA patients and controls). Three models were tested: a crude model with SAF as the sole determinant, an adjusted model 1 with SAF and cardiovascular comorbidity (presence of CVD and CAD), and an adjusted model 2 with SAF, cardiovascular comorbidity, and risk factors of AAA (ie, sex, current smoking, hypertension and use of lipid-lowering drugs). The logistic regression models were intrinsically adjusted for the matched variables, (age and DM). PAD was not included in the models because the controls were selected on the absence of PAD. The statistical analyses were performed using SPSS software version 22.0 (IBM, Armonk, NY).

RESULTS

Characteristics of patients. Of the 268 patients with AAA who were eligible to participate, 20 were excluded due to an inflammatory (n = 1) or mycotic aneurysm (n = 1), recent cardiovascular event (n = 2), end-stage renal disease (n = 2), solid-organ transplantation (n = 2), or active cancer (n = 12; Fig 1). The remaining 248 AAA patients were matched for age and presence of DM with 124 controls. Surgical repair of the aneurysm had been performed in 160 AAA patients (65%), 27 (11%) of which were performed because of rupture of the aneurysm. The median preoperative diameter of the aneurysm was 60 mm (IQR, 55-70 mm). In the patients who had not undergone surgical repair, the median diameter was 48 mm (IQR, 42-57 mm). The diameter of the aorta was not measured preoperatively in 26 patients (10%) due to emergency repair of a ruptured AAA (n = 9) or because the operation was performed in a different hospital without traceable information on diameter (n = 17). Median time between surgery and inclusion date was 3.20 years (IQR, 1.00-7.39 years). In nine AAA patients (4%), simultaneous aneurysms were found in other locations in addition to the abdominal aorta, comprising the iliac artery (n = 4), popliteal artery (n = 2), thoracic aorta (n = 1), femoral artery (n = 1), and carotid artery (n = 1).

Characteristics of the AAA patients and controls are summarized in Table I. Patients and controls had a...
mean age of 73 ± 7 years (range, 55-90 years in AAA patients and 57-90 years in controls). A higher proportion of AAA patients were men compared with controls (92% vs 41%; *P* < .0001). DM was present in 17% of the AAA patients and controls. Occurrence of hypertension did not differ between groups, but the mean systolic and diastolic blood pressures were lower in the AAA patient group than in the control group (*P* < .0001 and *P* = .013, respectively). The use of lipid-lowering and anticoagulant drugs was higher in the AAA patients than in the controls (*P* < .0001 for both). CAD and PAD were more common in AAA patients (*P* < .0001 for both), but the proportion of patients with CVD did not differ.

**SAF results.** SAF was significantly higher in AAA patients vs controls, at 2.89 ± 0.63 vs 2.68 ± 0.63 arbitrary units (*P* = .003; Table I, Fig 2). Within the AAA patients, SAF was higher in the patients with PAD than in the patients without PAD (*P* = .01 by univariable analysis, Fig 2). In a multivariable analysis of SAF, PAD remained a significant determinant (Table II).

In the AAA patients, multivariable linear regression analysis showed that age, current smoking, hypertension, eGFR, and PAD were significant determinants of SAF (adjusted *R*² = 0.10; Table II). Sex, presence of DM, body mass index, use of lipid-lowering drugs, anticoagulant therapy, aortic diameter, and a history of CAD or CVD were not determinants of SAF in the AAA patients. SAF levels did not differ between AAA patients who had not undergone surgical repair, AAA patients who had undergone open repair, and AAA patients who had undergone endovascular repair (Supplementary Fig, online only).

Journal of Vascular Surgery
Table III reports the result of the logistic regression models that describe the association between SAF and the presence of AAA in the total cohort. In the crude model, SAF was associated with presence of AAA (odds ratio [OR], 1.74; 95% confidence interval [CI], 1.20-2.51). After correction for cardiovascular comorbidity (presence of CAD or CVD), this association remained significant (OR, 1.78; 95% CI, 1.22-2.60; adjusted model 1). After additional correction for cardiovascular risk factors in adjusted model 2 (sex, current smoking, hypertension and use of lipid-lowering drugs), the association lost its significance (OR, 1.53; 95% CI, 0.94-2.48).

**DISCUSSION**

This study shows that SAF, as a measure of skin accumulation of AGEs, is increased in patients with AAA compared with controls. Furthermore, the association of SAF with AAA disease is independent of the presence of cardiovascular comorbidity. Still, within the AAA patients, SAF is closely associated with the presence of PAD and cardiovascular risk factors.

In several cardiovascular risk groups and disease, such as renal insufficiency, DM, CAD, and PAD, AGE levels are increased compared with controls. The present study adds AAA patients as a group at high cardiovascular risk with increased accumulation of AGEs. We found the association between SAF and AAA to be independent of the presence of CAD and CVD. Earlier studies on the association between AAA and AGEs are scarce. A study of eight AAA patients found that AGEs and receptor for AGE in the aortic wall were increased compared with five control samples from a tissue bank of autopsy materials. The same report described a reduction in the incidence of AAA of 50% in AGE receptor-knockout mice compared with control mice. In contrast, another study of 60 AAA patients with and without DM showed a lower pentoside content in the aortic aneurysm wall compared with 26 aortic control samples with and without DM. These differences in results may be explained by the type of AGEs that were measured: the latter study only measured the cross-linking AGE pentosidine, whereas the former study measured total AGEs content. In our present study, we used SAF to assess AGEs accumulation, which is correlated to the level of both cross-linking and noncross-linking AGES. Another explanation for the discrepancy between the above-mentioned studies may be the nature of the control samples, since these were taken from autopsy specimens. Whether accumulation of AGEs changes after death is unknown. Finally, it is possible that AGEs exert a double-sided effect on AAA development. On the one hand, AGEs might stimulate AAA progression by inducing endothelial dysfunction, calcification, loss of compliance, and thrombogenesis. On the other hand, cross-linking AGEs might have a protective effect on aneurysm growth through stiffening of the vascular wall. A recent study in a mouse AAA model confirmed that homogenous aortic stiffening reduces aneurysm growth.

The association we found between SAF and AAA was partly explained by the presence of cardiovascular risk factors. Although smoking is a confounding factor in this analysis, contributing to the generation and accumulation of AGEs while also being a known risk factor for AAA, this cannot fully negate this interaction. Therefore, we concluded that SAF in AAA patients is closely associated with cardiovascular risk factors and coexisting PAD rather than being solely associated with the presence of AAA disease. This is in line with earlier reports on increased SAF in PAD patients and increased SAF in patients with carotid artery disease that was mainly explained by the coexistence of PAD.

Interestingly, we found a lower prevalence of DM in AAA patients than in our earlier report on PAD patients. This observation is in line with a systematic review showing a reduced rate of diabetes in AAA patients. Possibly, diabetes exhibits a protective effect on AAA development through increased arterial stiffness induced by cross-linking of AGES. In the earlier mentioned study, AAA samples of diabetic patients showed a higher level of the cross-linking AGE pentosidine than AAA samples from nondiabetic individuals.
which correlated negatively with AAA diameter. To further elucidate the possible role of AGEs in the inverse association of DM with atherosclerotic diseases vs AAA, we designed the ARTERY (Advanced glycation end-products in patients with peripheral artery disease and abdominal aortic aneurysm) study. In this study, AGEs will be measured in aortic and macrovascular waste material in diabetic and nondiabetic subjects with AAA or PAD.

Although we showed that SAF is increased in AAA patients and remains associated with AAA disease after correction for cardiovascular comorbidity, more research is needed before conclusions can be drawn about the clinical implications of SAF measurements in AAA disease. Specifically, an investigation of the association between SAF and mortality, cardiovascular events, and growth or rupture of the aneurysm in AAA patients is necessary. Still, our findings contribute to the scarce knowledge available on AGEs accumulation in AAA disease.

Our study has several limitations. Firstly, the large proportion of patients who underwent surgical repair of the AAA before inclusion into the study shows that our population already had extensive disease. Also, the proportion of patients with CAD or CVD illustrates widespread atherosclerosis in these patients. Thus, our findings may not be representative for earlier stages of AAA.

Secondly, our controls were selected on the absence of a history and symptoms of AAA or PAD, whereas a proportion of our AAA patients did have concurrent PAD. Therefore, the comparison of SAF between AAA patients and controls could not be corrected for the presence of PAD. However, our multivariable linear regression analysis of SAF in the AAA patients showed that PAD is an important determinant. Although it is possible that a small proportion of our control subjects had undiscovered AAA or PAD disease, this would lead to an underestimation of the effect of SAF on AAA presence rather than an overestimation.

Thirdly, the cross-sectional design of this study did not permit conclusions to be drawn about the causality of the observed associations.

Fourthly, a limitation of the applicability of the AGE Reader is that it can only be used on individuals with skin pigmentation up to Fitzpatrick type V. In skin with higher pigmentation, excitation and emission light are both absorbed excessively by melanin, resulting in inaccurate SAF measurements.

Finally, levels of AGEs were only assessed by SAF and not directly in vascular tissues. The association between SAF and AGE content of human blood vessels has been investigated in patients with CAD, showing that SAF is correlated with the AGE content of cardiac tissue and venous bypass graft material. This grants probability to the possible association between SAF and AGEs in the human arterial wall in AAA patients.

**CONCLUSIONS**

SAF, as a noninvasive assessment of skin accumulation of AGEs, is increased in patients with AAA compared with controls, independent of cardiovascular comorbidity.

**Conclusion**

SAF, as a noninvasive assessment of skin accumulation of AGEs, is increased in patients with AAA compared with controls, independent of cardiovascular comorbidity.
Still, within the AAA patients, SAF is closely associated with the presence of PAD and cardiovascular risk factors. These findings suggest that accumulation of AGEs is increased in AAA patients, partly explained by presence of widespread atherosclerosis.
