Submitted.
Abstract

Prevention of infectious diseases is of high priority in the rapidly ageing population. Unfortunately, vaccine responses in the elderly are frequently diminished. Timely vaccination of middle-aged adults might improve the immune responses to vaccines, although knowledge on pathogen-specific immune responses and factors affecting these responses, in middle-aged adults is currently limited. We thus investigated the immune responses after VZV vaccination (Zostavax) in Dutch middle-aged adults.

Blood samples were taken pre-, 14 days, 28 days, and 1 year after a primary VZV vaccination (Zostavax) at middle-age (N=53, 50-65 years of age). VZV-specific IFNγ-producing cells were measured by Elispot, activated T-cells by flow cytometry, antibody levels and cytokine responses by fluorescent bead-based multiplex immunoassays, and whole blood cellular kinetics by TruCOUNT analysis.

Robust short-term enhancement of the VZV-specific IFNγ producing cell numbers was observed post-vaccination in the middle-aged adults. Remarkably, long-term enhancement of VZV-specific IFNγ producing cell numbers was induced only in participants with low numbers of VZV-specific pre-vaccination IFNγ producing cells, who were significantly older. These participants also showed enhancement of VZV-specific activated CD4 T-cells, contrary to ‘exhausted’ VZV-specific CD8 T-cells in participants with high numbers of VZV-specific pre-vaccination IFNγ producing cells. Finally, a high CD4/CD8 T-cell ratio was positively related to vaccine responsiveness.

These results suggest that adults in their early sixties, who showed a high CD4/CD8 T-cell ratio and low numbers of VZV-specific IFNγ producing cells, benefit from VZV vaccination. This provides important knowledge on factors affecting VZV-specific immune responses in middle-aged adults as well as for strategies to strengthen immunity before reaching old age.
Age-dependent pre-vaccination immunity affects the immunogenicity of Varicella Zoster vaccination

Introduction

Prevention of infectious diseases in the elderly is of high priority to establish healthy ageing in the rapidly ageing population. Unfortunately, vaccine effectivity in the elderly is low, leaving part of the elderly vulnerable for infections. Vaccination of middle-aged adults, before reaching old age, may be an alternative option to strengthen the memory immunity of the elderly. Currently, knowledge on pathogen-specific immune responses in middle-aged adults and factors affecting these immune responses is limited. Herpes zoster is an infectious disease with a large disease burden in the elderly. Yearly, approximately 3 to 5/1000 persons develop herpes zoster, also known as Shingles, of which the vast majority is of elderly age [1]. Herpes zoster is caused by reactivation of the latent varicella zoster virus (VZV), causing chickenpox after the first encounter during childhood [2]. The disease is characterized by painful rashes, mostly located at a single dermatome, which may develop into long-lasting complications such as post herpetic neuralgia [2, 3]. Advancing age and immune suppression are known as the strongest risk factors for herpes zoster, with a sharp increase in cases seen after the age of 50 [3-5]. Due to rapid ageing of the world population, the incidence of herpes zoster is likely to increase [1, 6-8]. Consequently, understanding the VZV-specific immune responses and factors affecting this immunity is crucial to decrease the herpes zoster disease burden.

VZV-specific cell mediated immunity (CMI) is essential in the protection against virus reactivation [9]. Particularly, VZV-specific IFNγ producing T-cells are seen as the best surrogate marker for protection against herpes zoster, although the exact number of protective cells remains to be established [10, 11]. A decline in VZV-specific CMI with age has been linked to increased susceptibility to virus reactivation and subsequent herpes zoster disease [12-15]. In contrast, the role of VZV-specific antibodies in the protection against herpes zoster is controversial, because contrary to CMI, VZV-specific antibody concentrations do not decrease with advancing age [13, 16]. Nevertheless, some studies suggest a positive correlation between antibody levels and protection against herpes zoster [10, 17].

In 2006 a live-attenuated vaccine, Zostavax, was licensed to prevent herpes zoster disease in persons of 50 years and older [18]. However, due to immunological ageing, vaccine efficacy strongly decreases with advancing age [10, 12, 19]. The low vaccine efficacy at old (> 65 years) age is one of the main reasons for a fierce debate about the implementation of the Zostavax vaccine in national vaccination programs. Consequently, solutions are warranted to decrease the herpes zoster disease burden in the elderly. Currently, a herpes zoster subunit vaccine containing VZV glycoprotein E and the AS01b adjuvant system is under regulatory evaluation after showing promising results in prevention of herpes zoster in the elderly [20-22]. Yet, knowledge on factors influencing vaccine induced VZV-specific immune responses during ageing is lacking.

In order to improve our understanding of VZV-specific immune responses, we investigated
the cellular and humoral immune responses after VZV (Zostavax) vaccination in middle-aged adults (50-65 years of age), an interesting target group for harnessing memory immunity before reaching old age. Moreover, we studied factors associated with vaccine immunogenicity in these middle-aged adults to be able to better predict the vaccine responses.

**Methods**

**Study design and participants**

Fifty three middle aged adults (50-65 years of age) were included in this phase IV single-centre and open-label study. Participants were invited in an urban area in the middle of the Netherlands in March 2015. Potential participants were excluded based on the following criteria: antibiotic use or fever (>38°C) within the last 14 days, diseases demanding immune suppressive treatment within the last 3 months, a known or suspected immune deficiency, a blood coagulation disorder, a neurologic disorder, administration of blood products in the past 6 months, serious surgery within the last 3 months, the use of hormone supplementation, a suspected allergy towards the vaccine components, a history of serious adverse events after previous vaccinations, a previous varicella zoster episode, a previous Zostavax vaccination, and any vaccination in the month before enrollment. Written informed consent was obtained from all participants prior to the study. All procedures were in accordance with the Declaration of Helsinki. The study was approved by the Medical Research Ethics Committees United (Mec-U) in Nieuwegein, the Netherlands (NTR4636).

**Vaccination and blood sampling**

All participants received a single dose of the live-attenuated varicella zoster vaccination (Zostavax; Sanofi Pasteur MSD), containing not less than 19400 PFU. The vaccine was subcutaneously administered. A blood sample was taken from all participants prior to the vaccination. Post-vaccination, blood samples were taken after 14 days, 28 days, and 1 year (Figure 1). Peripheral Blood Mononuclear cells (PBMCs) were isolated at all time points using vacutainer cell preparation tubes (CPT) containing sodium citrate (BD Biosciences), according to the manufacturer’s instructions [23]. Plasma samples were collected after initial spinning of the CPT tubes and were filtered using a Corning®Costar® Spin® X filter (Sigma-Aldrich) and were frozen at -20 before further use. After the initial collection, the PBMCs were washed with RPMI-1640 medium (Gibco) supplemented with 1% heat inactivated fetal calf serum (FCS, Gibco), 1% Penicillin and Streptomycin (Lonza). PBMCs were counted and frozen in a 90% FCS, 10% DMSO solution at -135°C until further use. Moreover, pre-vaccination, and at 14 and 28 days post-vaccination, an additional blood
sample was collected in tubes containing lithium heparin (BD) for detailed cellular immune phenotyping. Both the vaccinations and blood samplings were performed in the evening hours.

**Whole blood immune phenotyping**

The whole blood cellular immune phenotyping was performed within 18 hours after blood collection. Pre-vaccination, the absolute numbers of lymphocytes, monocytes, granulocytes, CD3+ T-cells, NK cells, B-cells and the different B-cell subsets (naïve mature, transitional, natural effector, memory B-cells, plasma cells) were determined with a lyse no-wash protocol using TruCOUNT tubes (BD). The following antibodies were used: CD3(UCHT1)-BV711, CD16(B73.1)-PE, and CD38(HB7)-APC-H7 (all from BD Biosciences), CD45(GA90)-OC515 and CD56(C5.9)-PE (both from Cytognos, Salamanca, Spain), CD27(M-T271)-BV421 and IgD(IA6-2)-FITC (both from Biolegend, San Diego, CA), and CD19(J3-119)-PE-Cy7 (Beckman Coulter, Fullerton, CA). Moreover, a detailed immune phenotyping was performed separately on the whole blood pre-vaccination samples using: CD4(RPA-T4)-BV510, CD45RA(H100)-BV605 and CD28(CD28.2)-PerCP-Cy5.5 (all from Biolegend), CCR7(150503)-PE-CF594, CD8(SK1)-APC-H7, CD25(2A3)-FITC, TCRgd(11F2)-PE-Cy7, and CD127(hIL-7R-M21)-PE (all from BD Biosciences), and CXCR5(51505)-APC (R&D systems, Minneapolis, MN). Absolute numbers of T-cell subsets were calculated using the CD3+ T-cell numbers from the TruCOUNT analysis. In addition, 14 and 28 days post-vaccination whole blood TruCOUNT analysis was performed using the following antibodies: CD27(M-T271)-BV421, CD45RA(H100)-BV605, IgD(IA6-2)-FITC, CD8(SK1)-FITC, CD4(OKT4)-PerCP-Cy5.5 (all BioLegend), CD3(UCHT1)-BV711, CD25(2A3)-PE, CCCR7(150503)-PE-CF594, TCRgd(11F2)-PE-Cy7, and CD38(HB7)-APC-H7 (All BD Biosciences), CD45(GA90)-OC515 (Cytognos), CD19(J3-119)-PE-Cy7 (Beckman Coulter, and CXCR5(51505)-APC (R&D systems). Gating strategies for the different cell subsets were applied as previously described [24]. Flow cytometric analyses were performed on a 4-laser LSR Fortessa (BD Biosciences) using standardized measurement settings [25], and data analysis using FacsDiva V8 (BD Biosciences) and FlowJo V10 (FlowJo company, Ashland, OR).

**VZV-specific IFNy and GrzB Elispot**

Multiscreen 96-wells Elispot plates (Merck Millipore) were shortly activated with 70% ethanol after which they were thoroughly washed with PBS (Tritium Microbiology) and either coated with anti-human IFNy antibody 1-D1K or anti-human GrzB GB10 (1 mg/ml; Mabtech). The coated plates were kept overnight at 4°C. The next day the plates were blocked with AIM-V medium (ThermoFisher) containing 5% human AB serum (Sigma Aldrich), hereafter called T-cell medium, for at least 1 hour at 37°C to avoid non-specific binding. The same batch of human AB serum was used for all samples in order to avoid differences in antigen
concentration during T-cell stimulation. After a quick thawing of the PBMCs in T-cell medium, PBMCs were thoroughly washed and distributed in concentrations of $3 \times 10^5$, $1.5 \times 10^5$ and $7.5 \times 10^4$ cells/well over the pre-coated IFNγ or GrzB plates. The PBMCs were stimulated with the mock (negative control), 6 μg/mL VZV-specific purified antigen (VZ10 strain; Genway), or 1μg/mL Staphylococcus aureus enterotoxin B (SEB, positive control) (Sigma Aldrich), again in a 3-fold dilution. All stimulations were performed in duplicate. All time points of one participant were tested on the same Elispot plate, to reduce assay variation. The plates were incubated for 48 hours at 37°C with 5% CO₂. Next, supernatants of the stimulated cells were collected and frozen at -80°C. Subsequently, the plates were washed thoroughly and incubated for 2 hours at 37°C with either mouse anti-human IFNγ antibody 7-B6-1 or mouse anti-human GrzB antibody GB11 (both Mabtech). After a washing step, a mixture containing Extravidin–alkaline (Sigma Aldrich) was added for 1 hour at room temperature. Finally, plates were washed and spots were developed by addition of a SIGMAFAST™ BCIP/NBT (Sigma Aldrich) solution. After drying, plates were scanned with the Epson ELISPOT Scanner and the spots were counted with a standardized protocol using the AELVIS software. Numbers of VZV-specific IFNγ and GrzB producing cells are presented per 10⁶ PBMCs after subtraction of the spots in the mock control. Mock controls on average contained 17 spots/10⁶ PBMCs for IFNγ and 20 spots/10⁶ PBMCs for GrzB. An NK-cell depletion experiment (using CD56 magnetic bead separation) was performed in order to estimate the contribution of NK cells in the IFNγ production as measured in the Elispot assays.

**VZV-specific IgG and IgA**

VZV-specific IgG concentrations (IU/mL) at the different time points were measured using a bead-based immunoassay as described previously [26]. VZV IgA concentrations (NTU) were measured using an enzyme-linked immunoassay (Genway Biotech, Inc., San Diego) according to the manufacturer’s instructions.

**CMV serology**

CMV IgG concentrations were determined in the plasma samples using an enzyme-linked immunoassay (ETI-CYTOK-G Plus, P002033, Diasorin, Salugga, Italy) according to the manufacturer’s indications and as described earlier [24].

**VZV-specific T cell activation and IFNγ production**

PBMCs were thawed as before. Thereafter, 10⁶ cells/well were stimulated with mock (negative control) or 6 μg/mL VZV-specific purified antigen (VZ10 strain; Genway) in a 48 well plate. Moreover, 5*10⁵ cells/well were stimulated with 1μg/mL SEB (positive control) (Sigma Aldrich). The cells were incubated for 72h at 37°C with 5% CO₂. During the last 5
hours GolgiPlug protein transport inhibitor containing Brefeldin A (1000x dilution, BD) was added to each well. After a thorough washing, cells were incubated for 30 minutes with a mixture of Life-Death Zombie Aqua fluorescent dye (Biolegend) and surface antibodies in FACS buffer, containing PBS with 0.5%BSA and 2mM EDTA. The following antibodies were used for surface staining: CD3(SK7)-PerCP, CD4(RPA-T4)-ACP, CD45RA(L48)-PE-Cy7, CCR7(3D12)-BV605, CD56(NCAM16.2)-BV711 (all BD), CD38(HIT2)-BV786 (Biolegend), CD8(CLBT8/4,H8)- FITC (Sanquin), and HLA-DR(LN3)-APCfluor780 (ebiosciences). Subsequently, cells were washed with PBS, and permeabilized for 20 minutes with Cytofix/Cytoperm (BD). A Perm/Wash solution (BD) was used to wash the cells. In addition, the cells were stained for 30 minutes with IFNγ (25723.11)-PE. After an additional washing step, the cells were resuspended in FACS buffer and immediately measured on a 4-lazer LSR Fortessa (BD) and the data was analyzed using FlowJo V10. Frequencies of activated (CD38+HLA-DR+) and CD4+IFNγ+ (data not shown) VZV-specific cells were calculated after subtraction of the mock control.

Cytokine detection in supernatants
After 48 hours of PBMC stimulation, IL2, TNFα, IL5, IL13, and IL10 concentrations in the supernatants were determined as previously described [27]. Samples with concentrations below the lower limit of quantification were assigned half the concentration of the lowest measurement. Cytokine concentrations in the mock controls were subtracted from those in the antigen stimulated samples.

Statistics
Only complete cases, with measurements at all different time points, were used for analysis. The numbers of VZV-specific IFNγ producing cells, cytokine concentrations, activated cells, and the whole blood TruCOUNT responses at the different time points were compared with the Wilcoxon signed rank test, preceded by the Friedman test. The VZV-specific IgG and IgA responses were log-transformed after which the ANOVA was used to compare the different time points. Corrections for multiple testing were used as indicated under the figures/tables. Participants with low and high pre-vaccination immunity were compared at all time points by using the Mann Whitney U test. Correlations were determined by the Spearman’s rho correlation test. Geometric means with the 95% confidence intervals (CI) were indicated in the graphs. The boxplots used in the figures are plotted from the min to max values with indication of the median. The whole blood absolute cell numbers were compared at the different time points between the participants with low and high pre-vaccination CMI with the Mann Whitney U test. The geometric means of these groups were normalized to z-scores using the geometric means.
and standard deviation of the total group to be presented in the heat maps. Graphpad V7 and SPSS V22.0 were used.

Results

Participant characteristics

A total of 53 middle-aged adults participated in this study (mean age: 57.6; range 50-65; 66% male) (Figure 1). After a pre-vaccination blood drawing, all participants received the Zostavax vaccine. Follow-up blood samples were drawn at 14 days, 28 days, and 1 year post-vaccination. Finally, 49 (92.5%) of the participants completed the study. Additional participant health characteristics are presented in S. Table 1. Due to sample availability distinct numbers of participant samples were used for the various assays (Figure 1).

Figure 1. Participants flow chart.
Robust short-term VZV-specific cellular and humoral vaccine responses in middle-aged adults

Pre-vaccination, highly variable numbers of VZV-specific IFNγ producing cells per 10⁶ PBMCs were observed in the circulation of middle-aged adults (geometric mean 53.4 [35.8 – 79.6]) (Figure 2a). These cells significantly increased shortly after vaccination (14 days: geometric mean 101.6 [79.0 – 130.8]; 28 days: geometric mean 115.9 [94.5 – 142.3]) and returned to baseline values one year post-vaccination (geometric mean 71.5 [55.1 – 92.8]) (Figure 2a). A preliminary NK cell depletion experiment indicated that the majority of this IFNγ was produced by the T-cells (data not shown).

All participants possessed pre-vaccination IgG antibody concentrations above the VZV seropositivity level of 0.26 IU/ml, as established by van Lier et al. [16] (geometric mean 2.0 [1.7 – 2.5]), indicative of previous infection with the VZV virus in all participants (Figure 2b). These VZV-specific IgG antibodies were found significantly increased at days 14 (geometric mean 12.4 [9.2 – 17.6]) and 28 (geometric mean 8.2 [6.1 – 11.1]) post-vaccination. Similar to the IFNγ T-cell responses, no significantly elevated IgG responses were observed 1 year post-vaccination (geometric mean 2.5 [1.9 – 3.1]) (Figure 2b).

Importantly, we observed a negative correlation between pre-vaccination VZV-specific IFNγ producing cells and the fold change in VZV-specific IFNγ producing cells post-vaccination (14 days: rho: -0.669, 28 days: rho: -0.714, 1 year: rho: -0.610; all p<0.0001). We did not observe
correlations between the cellular and humoral responses, indicating that these responses develop independently (data not shown).

**Long-term enhancement of VZV-specific IFNγ producing cell numbers in participants with low pre-vaccination CMI**

Since we observed a negative correlation between the numbers of pre-vaccination IFNγ producing cells and the vaccine-induced increase in these cells, we determined whether differential vaccine responses were observed in participants with low and high numbers of pre-vaccination VZV-specific IFNγ producing cells (Figure 3), hereafter called participants with low and high pre-CMI. The median number of pre-vaccination spots was determined and participants below the median were considered to have low pre-CMI whereas participants above the median were considered to have high pre-CMI. Remarkably, only participants with low pre-CMI showed enhancement of the number of IFNγ producing cells post-vaccination which was maintained up until 1 year (fold change 14 days: 2.7, 28 days: 4.3, and 1 year: 2.2) (Figure 3a). On the contrary, numbers of IFNγ producing cells were not significantly enhanced post-vaccination in participants with high pre-CMI (fold change 14 days: 1.3, 28 days: 1.1, and 1 year: 0.8) (Figure 3a). One year post-vaccination, some of these participants even showed trends towards reduced numbers of IFNγ producing cells compared to pre-vaccination. Interestingly, participants with low pre-CMI were significantly older than the participants with high pre-CMI, even within this small age-range (Figure 3b).

The two groups showed similar IgG concentrations (S. Figure 1a), confirming the independence of the VZV-specific IgG and CMI responses. Noteworthy, IgA responses significantly differed between the two groups, with stronger responses seen in the participants with low pre-CMI (S. Figure 1b).

In order to enlarge our understanding of the difference in T-cell responses between the participant with low and high pre-CMI, we compared the production of several cytokines in the cell culture supernatants after 48 hours of culture. Significant differences were found between the two groups in VZV-specific Th1 and Th2 cytokines. Post-vaccination, significant enhancement of the VZV-specific IL2, TNFα, IL13, and IL5 secretion was observed in the low pre-CMI group, whereas no significant responses were found in the high pre-CMI group. Noteworthy, no significant IL10 and Granzyme B (GrzB) responses were observed in both groups (S. Figure 2).

Overall, our results indicate strong VZV-specific cytokine and IgA responses in the circulation of middle-aged adults with low pre- VZV-specific CMI, whereas this response was absent in the circulation of adults with high pre-CMI. Importantly, a low pre-CMI was associated with higher age in this group.
Age-dependent pre-vaccination immunity affects the immunogenicity of Varicella Zoster vaccination

IFNγ producing cells per 10⁶ PBMCs

Figure 3. VZV-specific responses in participants with low and high pre-vaccination IFNγ producing cells.

(a) The number of VZV-specific IFNγ producing cells, as measured by Elispot, in participants with low (white boxplots, N = 19) and high (grey boxplots, N= 20) pre-vaccination IFNγ producing cells. These groups were determined using the median number of pre-vaccination IFNγ producing cells. Participants in the low pre-vaccination group possessed numbers of VZV-specific IFNγ producing cells below the median, compared to numbers above the median in the high pre-vaccination group. (b) The age distribution of participants with low and high pre-vaccination IFNγ producing cells. All boxplots are plotted from the min to max values with indication of the median. The low and high responders were compared with the Mann Whitney U test. The different time points were compared with the Wilcoxon signed rank test preceded by the Friedman Test with correction for multiple testing. *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001.

Differential responses in VZV-specific activated (CD38+HLA-DR+) T-cells post-vaccination in participants with low and high pre-CMI

Subsequently we investigated the frequencies of VZV-specific activated T-cells, both within the CD4 and CD8 T-cell compartment. Activated cells were based on the double expression of HLA-DR and CD38 (gating strategy in S. Figure 3). Activated VZV-specific CD8 CM cells could not be detected, due to the low frequencies of these cells in the circulation [28]. We observed elevated frequencies of activated VZV-specific CD4 T-cells at 14 days and 28 days post-vaccination, mainly consisting of CM, TemRO and TemRA cells (Figure 4a). After 1 year, elevated frequencies of activated CD4 CM and TemRO cells were still found. The numbers of VZV-specific activated CD8 T-cells were significantly enhanced at all time points post-vaccination, and mainly consisted of TemRO and TemRA cells (Figure 4b). Remarkably, activated VZV-specific cell responses were significantly different between the participants with low and high pre-CMI (Figure 4 c-f). Participants with low pre-CMI showed strong enhancement of the activated VZV-specific CD4 cells (CM, TemRO and TemRA) and only a small enhancement of the CD8 TemRA response (Figure 4c and e). In contrast, participants with high pre-CMI showed a CD8 T-cell oriented response, with increased frequencies of VZV-specific CD8 TemRA cells up until 1 year (Figure 4f).
Figure 4. VZV-specific activated (CD38+HLA-DR+) T-cells

The VZV-specific frequency of activated T-cells (based on the double expression of CD38 and HLA-DR) in the CD4 (a) and CD8 (b) T-cell compartments in the total group of participants (N=20). The VZV-specific activated CD4 T-cells in participants with low (c) and high (d) pre-CMI. The VZV-specific activated CD8 T-cells in participants with low (e) and high (f) pre-CMI. The geometric mean values were used in the graphs. The different time points were compared to the pre-vaccination frequencies with the Wilcoxon signed rank test preceded by the Friedman test. The stars in the bars indicate significant differences for specific subsets as compared to the pre-vaccination levels, whereas the stars above the bars indicate differences in the total CD4+ of CD8+ VZV-specific activated cells as compared to the pre-vaccination time point. *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001.
However, 1 year post-vaccination, this group also showed some enhancement of the VZV-specific CD4 CM T-cells (Figure 4d). Overall these responses suggest differential induction of T-cell responses in participants with low and high pre-CMI, with a more CD4 T-cell oriented response in participants with low pre-CMI as compared to a more CD8 TemRA oriented response in participants with high pre-CMI.

**Whole blood lymphocyte subset kinetics mirror the differential vaccine responses in participants with low and high pre-CMI**

Finally, we determined whether the blood leukocyte responses were different between participants with low and high pre-CMI (S. Figure 4 and Figure 5a).

![Figure 5. Comparison of leukocyte subset kinetics between adults with low or high pre-CMI.](image)

- **(a)** Comparison of the whole blood absolute immune cell numbers between participants with low and high pre-CMI at the pre- as well as 14 and 28 days post-vaccination time points. The absolute cell numbers were normalized to z-scores, using the geometric means of the low and high group respectively. Z-scores ranged from -0.5 to 0.5. The normalized z-scores are displayed on a colour scale, ranging from blue (geometric means below the geometric mean of the total group), to red (geometric means above the geometric mean of the total group). The white colour indicates values equal to the group geometric mean. The stronger the deviation from the group geometric mean, the darker the colour. Comparison of the CD4 naïve cells (b), CD4 TemRA cells (c), B-cells (d), naïve B-cells (e), and the CD4/CD8 ratio (f) TruCOUNT kinetics between the participants with low or high pre-vaccination CMI. The groups were compared per subset with the Mann Whitney U test. *p<0.05, **p<0.01.
Pre-vaccination, a significant difference was found in the CD4/CD8 T-cell ratio between the 2 groups: participants with low pre-CMI in general possessed a CD4/CD8 ratio above 3, whereas participants with high pre-CMI showed a ratio below 3. This possibly suggests a compositional difference in the immune phenotype between participants with low and high pre-CMI. Participants with low pre-CMI showed slightly higher numbers of CD4 T-cells (mainly naïve cells), whereas participants with high pre-CMI showed slightly higher numbers of CD8 T-cells. This difference in CD4/CD8 T-cell ratio continued to exist at the different time points after vaccination (Figure 5a and f). Correspondingly, at 14 days post-vaccination, significantly higher numbers of circulating CD4 naïve cells, CD4 TemRA cells, B-cells, and naïve mature B-cells were found in the participants with low pre-CMI (Figure 5a-e). This result indicates differential lymphocyte subset kinetics in participants with low and high pre-CMI 14 days post-vaccination and therefore suggests that these responses can be used as a short-term biomarker to predict the long-term vaccine responses in middle-aged adults.

**Discussion**

Our study showed that the pre-vaccination VZV-specific cellular immunity highly affects the VZV vaccine induced immune responses in middle-aged adults. Robust long-term increases in VZV-specific CMI, here defined as the numbers of IFNγ producing cells, were observed post-vaccination in participants with low pre-CMI, whereas no significant enhancement was observed in participants with high pre-CMI. Participants with low pre-CMI mainly showed long-term enhancement of activated (based on the double expression of CD38 and HLA-DR) CD4 T-cells, while participants with high pre-CMI demonstrated increased proportions of activated VZV-specific CD8 TemRA cells, suggesting exhaustion of the VZV-specific T-cell response. Interestingly, the middle-aged participants with low pre-CMI were generally older than participants with high pre-CMI and had a higher CD4/CD8 T-cell ratio (>3). Based on these findings, we propose that next to age, pre-vaccination VZV-specific CMI and a high CD4/CD8 T-cell ratio (>3) are predictive for a productive immune response to VZV vaccination at middle-age. Moreover, whole blood kinetics, as found in the absolute numbers of CD4 naïve cells, CD4 TemRA cells, B-cells, and naïve mature B-cells 14 days post-vaccination, might be used as a quick short-term predictive parameter for the long-term enhancement of VZV-specific CMI.

Previously, a large study (N=22,439) in Northern America and Europe estimated the efficacy of the Zostavax vaccination at 50-59 years of age to be approximately 70% [29]. This efficacy sharply declined towards older age groups [10, 19], suggesting possible benefits of timely vaccination to boost the VZV-specific CMI before reaching old age. Since childhood varicella vaccination has been implemented in the national immunization program of several countries across Europe as well as the US, the VZV-specific epidemiology in these countries...
Age-dependent pre-vaccination immunity affects the immunogenicity of Varicella Zoster vaccination

significantly differs from those not vaccinating against VZV [5, 16, 30]. Consequently, the immune responses to the Zostavax vaccine in middle-aged adults as investigated in countries with childhood VZV vaccination should not be directly extrapolated to our study population, in which VZV-specific CMI is more frequently boosted by external natural virus circulation. Despite these epidemiological differences, our results show similar short-term enhancement of the VZV-specific CMI in the circulation of middle-aged adults as was observed previously [31].

Yet, the differential peripheral responses in participants with low and high pre-CMI are remarkable and suggest that only middle-aged adults with low pre-vaccination CMI benefit from additional immunization. Interestingly, more participants in their early sixties were found in the low pre-CMI group, consistent with the general decrease in VZV-specific immunity found with advancing age. Based on these findings, we speculate that VZV vaccination might be more beneficial for participants in their sixties.

On the contrary, the vaccination might exhaust the VZV-specific T-cell pool in participants in the early fifties, due to high levels of VZV-specific pre-CMI. These participants showed long-term enhancement of the terminally differentiated CD8 TemRA cells, and a very small enhancement of CD4 CM cells. This finding may be the result of frequent natural boosting in these participants, possibly exhausting the phenotype of VZV-specific T-cells. An additional VZV vaccination of participants with already high levels of pre-vaccination VZV-specific CMI thus seems not productive and might unintentionally cause exhaustion of the VZV-specific T-cell pool, although a beneficial effect of these cells in the prevention of viral replication cannot be excluded [32]. Of note, the vaccination did not induce elevated IL10 production or elevated numbers of circulating Treg cells in the participants with high pre-CMI, suggesting that the vaccine did not affect the suppression of the immune response in these participants.

These large effects of the pre-vaccination VZV-specific CMI on the VZV-specific vaccine response requires additional investigation in order to improve our understanding of VZV-specific cellular immune responses and consequently improve the protection of older adults against herpes zoster disease. Since this pre-vaccination immunity in middle-aged adults may be different between countries with and without childhood varicella vaccination, it is of interest to compare the cellular immune responses obtained from this study, with that in middle-aged adults from a country with high childhood VZV-vaccination coverage. Importantly, a herpes zoster adjuvanted subunit vaccine containing the recombinant glycoprotein E is under evaluation for registration, after showing an efficacy rate of 97.2% in protection against herpes zoster disease of the elderly [20-22]. In order to further improve our understanding of factors affecting VZV-specific immune responses, it would also be of interest to investigate the effects of pre-vaccination immunity on the T-cell responses initiated by this vaccine.
In addition, we are the first reporting an association between the CD4/CD8 T-cell ratio and VZV-specific CMI. Interestingly, we observed a significantly higher CD4/CD8 T-cell ratio (>3) in participants with low pre-vaccination CMI, suggesting a difference in the immune phenotype between the two groups. Considering the significantly higher age of the participants with low pre-CMI in our study population, our results confirm and extend the observation of a general increase in the CD4/CD8 T-cell ratio with advancing age, as previously shown by others [33]. The higher CD4/CD8 T-cell ratio, above 3, perhaps indicates immune competence in participants with low pre-vaccination VZV-specific CMI, and thereby predicts which participants are eligible for timely VZV vaccination. Larger cohort studies are needed to confirm this observation. Of note, we did not observe a negative correlation between the numbers of Treg cells or late-differentiated CD4 T-cells and the VZV vaccine response, as was previously found in nursing home elderly [34]. This difference might be explained by the low number of participants in our study.

Our study is limited by the measurement of VZV-specific CMI in the circulation only, which is likely to have a different cellular composition compared to tissue sites [28, 35]. For example, a distinct effect of age was found on peripheral T-cells as compared to other compartments [35]. Specifically, in contrast to an age related decrease in VZV-specific CD4 T-cell numbers in the circulation, no age related decrease was found in the skin [15]. In our study, it cannot be excluded that participants with high circulatory levels of VZV-specific CMI might show enhancement of VZV-specific CD4 T-cells in the skin, and therefore benefit more from the vaccination than concluded based on the analysis of the peripheral immune response. Moreover, the long-term immunogenicity of this study has to be confirmed by additional sampling of the participants at older age, years after vaccination, in a comparative study with elderly persons who did not receive an additional vaccination.

In conclusion, we found long-term beneficial effects of VZV (Zostavax) vaccination on the VZV-specific CMI in the circulation of middle-aged adults with low pre-vaccination CMI. Moreover, age (>60 years) and a high CD4/CD8 T-cell ratio (>3) were found predictive for the presence of low VZV-specific pre-CMI. More studies in independent cohorts are required to substantiate these findings. Our results suggest that in a population with high levels of natural VZV boosting, vaccination against herpes zoster is more beneficial in the early sixties and thereby adds important knowledge for the further development of strategies to prevent the high herpes zoster disease burden in the ageing population.

**Acknowledgements**

We thank all the participants of the study and the nurses who performed the vaccinations and blood drawings. Moreover, we thank Joris Roggekamp and Sophinus Bartol for the excellent help with the laboratory analysis and Wilco de Jager for sharing his laboratory expertise. Finally, we thank Cecile van Els for critical reviewing of the manuscript.
Age-dependent pre-vaccination immunity affects the immunogenicity of Varicella Zoster vaccination

Supplementary Figure 1. VZV-specific antibody levels pre- and post-vaccination in participants with low and high pre-vaccination IFNγ producing cells.

The IgG (a) and IgA (b) levels in participants with low (white boxplots) and high (grey boxplots) pre-CMI. All boxplots are plotted from the min to max values with indication of the median. The geometric mean concentrations with 95% CI were indicated in the graphs. The participants with low and high pre-CMI were compared with the Mann Whitney U test. *p<0.05, **p<0.01.
Supplementary Figure 2. VZV-specific cytokine secretion in cell culture supernatant from participants with low and high pre-CMI.

Concentrations (pg/ml) of VZV-specific IL2 (a), TNFα (b), IL10 (c), IL13 (d), and IL5 (e) in cell culture supernatant after 48h of stimulation with VZ10 in participant with low (white boxplots) N=10 and high (grey boxplots) N=9 pre-CMI. (f) The number of GrzB producing cells per 10⁶ PBMCs pre- and post-vaccination in participants with low (white boxes) N=11 and high (grey boxes) N=9 pre-CMI as measured by the Elispot assay. The bars were plotted from the min to the max values, with the middle-line indicating the median. The participants with low and high pre-CMI were compared with the Mann Whithney U test at all different time points. The different time points were compared with the Wilcoxon signed rank test preceded by the Friedman test for the participants with low and high pre-CMI separately. *p<0.05, **p<0.01, ***p<0.001.
Supplementary Figure 3. Gating strategy of the activated CD4 T-cell subsets.

The VZ10 specific activated cells (based on the double expression of CD38 and HLA-DR) in the different CD4 T-cell subsets representative to the negative mock control and the positive (SEB) control from a representative sample 14 days post-vaccination.
Supplementary Figure 4. Leukocyte subset numbers pre- and post-VZV vaccination in middle-aged adults.

Absolute numbers of leukocyte subsets (a), CD4 T-cell subsets (b), CD8 T-cell subsets (c), and B-cell subsets (d) pre- and 14 days, and 28 days post-vaccination, N = 49. (a) The absolute numbers of all subsets were significantly elevated 14 days post-vaccination (lymphocytes: p = 0.0001, monocytes: p = 0.0002, granulocytes: p = 0.0025, CD3: p = < 0.0001, CD4: p = 0.0002, CD8: p = < 0.0001, B-cells: p = 0.0006), and were reduced to baseline levels again after 28 days. (b) The absolute numbers of all subsets were significantly elevated 14 days post-vaccination (CD4 naive: p = 0.009, CD4 CM: p = < 0.0001, CD4 TemRO: p = 0.007, CD4 TemRA: p = 0.0001, CD4+CXCR5+: p = 0.007, Treg: p = < 0.0001). After 28 days, the absolute numbers of CD4 TemRO (p = 0.02) and CD4+CXCR5+ (p = 0.007) were significantly lowered compared to baseline levels. Treg (p = < 0.0001) cell numbers were significantly elevated after 28 days. (c). The absolute numbers of all subsets were significantly elevated after 14 days (CD8 naive: p = 0.0002, CD8 CM: p = < 0.0001, CD8 TemRO: p = 0.0002, CD8 TemRA: p = 0.05, TCRgd: p = < 0.0001). The absolute numbers of CD8 CM cells were significantly elevated after 28 days (p = 0.002), and the absolute numbers of CD8 TemRA cells significantly decreased (p = 0.004). (d). The absolute numbers of naive mature (p = 0.008), natural effector (p = 0.004), CD27-MemB (p = 0.003), and CD27+MemB (p = < 0.0001) were significantly elevated after 14 days. The absolute numbers of transitional cells were significantly decreased after 28 days (p = 0.0001). The absolute numbers at the 14 days and 28 days post-vaccination time points were compared to the pre-vaccination levels with the Wilcoxon signed rank test preceded by the Friedman test and were corrected for multiple comparisons.
