ABSTRACT

Context. Mid-IR water lines from protoplanetary disks around T Tauri stars have a detection rate of 50%. Models have identified multiple physical properties of disks such as dust-to-gas mass ratio, dust size power law distribution, disk gas mass, disk inner radius, and disk scale height as potential explanations for the current detection rate.

Aims. In this study, we aim to break degeneracies through constraints obtained from observations. We search for a connection between mid-IR water line fluxes and the strength of the 10 \( \mu \)m silicate feature.

Methods. We analyze observed water line fluxes from three blends at 15.17, 17.22 and 29.85 \( \mu \)m published earlier and compute the 10 \( \mu \)m silicate feature strength from Spitzer spectra to search for possible trends. We use a series of published ProDiMo thermochromical models, to explore disk dust and gas properties, and also the effects of different central stars. In addition, we produced two standard models with different dust opacity functions, and one with a parametric prescription for the dust settling.

Results. Our series of models that vary properties of the grain size distribution suggest that mid-IR water emission anticorrelates with the strength of the 10 \( \mu \)m silicate feature. The models also show that the increasing stellar bolometric luminosity simultaneously enhance the strength of this dust feature and the water lines fluxes. No correlation is found between the observed mid-IR water lines and the 10 \( \mu \)m silicate strength. Two-thirds of the targets in our sample show crystalline dust features, and the disks are mainly flaring. Our sample shows the same difference in the peak strength between amorphous and crystalline silicates that was noted in earlier studies, but our models do not support this intrinsic difference in silicate peak strength. Individual properties of our models are not able to reproduce the most extreme observations, suggesting that more complex dust properties (e.g., vertically changing) are required to reproduce the strongest 10 \( \mu \)m silicate features. A parametrized settling prescription is able to boost the peak strength by a factor of 2 for the standard model. Water line fluxes are unrelated to the composition of the dust. The pronounced regular trends seen in the model results are washed out in the data due to the larger diversity in stellar and disk properties compared to our series of model.

Conclusions. The independent nature of the water line emission and the 10 \( \mu \)m silicate strength found in observations, and the modeling results, leave as a possible explanation that the disks with weaker mid-IR water line fluxes are depleted in gas or enhanced in dust in the inner 10 au. In the case of gas depleted disks, settling produces very strong 10 \( \mu \)m silicate features with strong peak strength. Observations of larger unbiased samples with JWST/MIRI and ALMA are essential to verify this hypothesis.

Key words. protoplanetary disks – line: formation – stars: pre-main sequence – circumstellar matter

1. Introduction

Water has been observed in protoplanetary disks from the near-IR (Salyk et al. 2008), through the mid-IR (Carr & Najita 2008; Pontoppidan et al. 2010a,b), to the far-IR (Hogerheijde et al. 2011; Podio et al. 2013; Riviere-Marichalar et al. 2012). The main water reservoir, with an abundance of 10\(^{-4}\) with respect to the total hydrogen number density, is located in the inner few au; this reservoir is responsible for water emission below 30 \( \mu \)m. A survey of mid-IR water lines has produced a complex picture: the detection rate of about 50% for T Tauri and 5% for Herbig stars (Pontoppidan et al. 2010a). Our previous work (Antonellini et al. 2015) found that the continuum opacity due to differences in dust properties is one of the main reasons for changing the strength of the mid-IR water emission. In a subsequent paper (Antonellini et al. 2016), we explain the non-detections of mid-IR water lines around early-type pre-main-sequence stars (PMSs), with the stronger mid-IR continuum and instrumental noise.

Dust is assumed to constitute only 1% of the disk mass, but it is a bolometric source of opacity able to suppress line fluxes. Dust also plays a role in the thermal balance of the disk, due to the photoelectric effect. In environments such as protoplanetary disks, dust grains grow (as inferred from mm flux and spectral indexes, Beckwith et al. 1990; Mannings & Sargent 2000; Andrews & Williams 2005, 2007) and settle (D’Alessio et al. 1999; Chiang et al. 2001). Silicate grains produce two solid state features around 10 and 20 \( \mu \)m. The features originate mainly from \( \mu \)m-sized grains where the dust temperature is around 200–600 K (Natta et al. 2007). The 10 \( \mu \)m feature hosts information about the thermal and physical history of dust grains, and...
also the composition (Kessler-Silacci et al. 2005). According to van Boekel et al. (2005), the more the dust is processed (crystallized), the wider the feature and the lower the peak strength. The strength of the 10 \( \mu m \) peak is also inversely correlated with the dust grain size. Bouwman et al. (2008) have found a correlation between the shape of the 10 \( \mu m \) amorphous feature and the SED shape, that is consistent with both dust growth and subsequent settling. Turbulent mixing, however, seems efficient in maintaining \( \mu m \)-sized grains in the atmospheres of T Tauri disks (Olofsson et al. 2009). Mass transport can also explain the presence of a relevant fraction of cold crystallized dust in disks around T Tauri stars (Olofsson et al. 2010). The correlations found between crystalline indexes and continuum spectral indexes considered in Watson et al. (2009) are consistent with the larger mass of crystalline silicates found in settled disks. In our previous work (Antonellini et al. 2015), we found the continuum opacity to be a main factor in IR water spectroscopy. The dust opacity depends on the size of the dust (both in terms of maximum size and size distribution) and its composition. Typical spectral features of silicates in mid-IR spectra are at \( \sim 10 \mu m \) and \( \sim 18 \mu m \); the exact wavelength depends on the composition (Jäger et al. 2003). The shape and intensity of these features are also related to the dust composition and size properties (e.g. Jaeger et al. 1994; Chiang et al. 2001; Bouwman et al. 2001; Min et al. 2011). This suggests the potential of a relation between the strength/shape of the strongest dust silicate feature (the \( 10 \mu m \)) and the mid-IR water lines. The presence of this correlation could open the possibility of a new diagnostic tool for the inner disk properties.

Water lines and the silicate features both arise from the inner disk. Hence, in this paper we investigate a potential relation between the mid-IR water lines and the 10 \( \mu m \) silicate feature strength. We investigate this in the context of the thermochemical modeling results by Antonellini et al. (2015, 2016) and compare these findings to a sample of disks observed with Spitzer.

### 2. Spitzer spectra

We analyze in this work Spitzer-IRS high \((R \approx 600)\) and low resolution \((R \approx 120)\) spectra of a sample of T Tauri stars. We considered T Tauri stars for which measurements of line fluxes for the blends at 15.17 \( \mu m \), 17.22 \( \mu m \), and 29.85 \( \mu m \) are available from Pontoppidan et al. (2010a). We then took spectra from the CASSIS database\(^1\) and reduced BCD data from the Spitzer archive\(^2\). We reduced the second set of high resolution data following a pipeline developed by the c2d team (Evans et al. 2009), and applied the PSF extraction procedure (Lahuis et al. 2007; Lahuis 2007). The data were then post-processed by applying defringing (Lahuis & Boogert 2003) to remove residuals due to low-level fringes. Spectra from CASSIS are all low resolution, and already reduced following a pipeline described in detail in Lebouteiller et al. (2011). The two pipelines produce spectra of comparable quality beside the different resolution.

The strength of the 10 \( \mu m \) silicate feature \( S_{\lambda,\text{peak}} \) is computed as

\[
S_{\lambda,\text{peak}} = \frac{F_{\lambda,\text{peak}} - F_{\lambda,\text{cont}}}{F_{\lambda,\text{cont}}},
\]

where \( F_{\lambda,\text{peak}} \) is the flux at 10 \( \mu m \) and \( F_{\lambda,\text{cont}} \) is the local linearly fitted continuum. The error computation is taken from the covariance matrix of the fitting function\(^3\).

The definition of silicate peak strength adopted in this work differs from that used in Olofsson et al. (2009), which is based on Kessler-Silacci et al. (2006). There, the peak strength is defined as

\[
F_{\text{peak}} = F_{\nu} - F_{\nu,\text{continuum}} - \langle F_{\text{continuum}} \rangle,
\]

where \( F_{\nu} \) is the spectral flux at the frequency of the peak, \( F_{\nu,\text{continuum}} \) is the fitted value for the continuum at the peak frequency, and \( \langle F_{\text{continuum}} \rangle \) is the average continuum in the fitted wavelength range \( \sim 7-14 \mu m \); the exact range of the fit is a function of the data range and SED slope. In addition to the \( +1 \) shift in the value of the peak (which systematically produces larger peak values with respect to our definition), the definition of the average continuum can produce a slight difference in the ratio, in particular in cases where our fitted range differs from the one adjusted for each specific case.

Figure 1 shows that our definition produces systematically weaker peak fluxes, but the deviation scatter from the red line is around one. In some cases, our selected spectra are from a different program, and some of the targets are known to be variable in the mid-IR. Olofsson et al. (2009) fluxes are from c2d spectra, and their values agree more closely with our peak fluxes in the case where we used c2d spectra as well. Agreement between the two peak strength definitions is on average better than 13%, meaning that any conclusion produced will be valid independently of the definition used for the silicate feature strength.

Individual targets, have different spectral types and luminosities; in our sample, the range of luminosity spans from 0.26 to 2.6 \( L_{\odot} \). To make a direct comparison between the observations and our models (which are built around a typical K7 star with

species with average ture of 80% amorphous silicates and 20% carbonaceous dust. The disk dust composition of our models is based on a mixing a single parameter each time. These models include a pre-non-LTE line radiative transfer. The series are built by changing thermo-chemical models, with continuous disk structure, and dust peak strength at 10 µm. The used in the last model series are different from the standard T Tauri, which is a K7 spectral type.

Notes. Bold numbers refer to standard model values. The central stars used in the last model series are different from the standard T Tauri, which is a K7 spectral type.

$L_\star = 0.7 L_\odot$, we divided the mid-IR water line fluxes by the local continuum flux.

3. Modeling water and silicates

We perform a parameter space exploration using a sub-series of the models presented in Antonellini et al. (2015, 2016), considering parameters significantly affecting mid-IR water line fluxes and dust peak strength at 10 µm (Table 1). These are 2D radiation thermo-chemical models, with continuous disk structure, and non-LTE line radiative transfer. The series are built by changing a single parameter each time. These models include a prescription of the dust settling based on Dubrulle et al. (1995). The disk dust composition of our models is based on a mixture of 80% amorphous silicates and 20% carbonaceous dust species with average $\rho = 3.5$ g/cm³ (Draine & Lee 1984), and the dust size distribution is based on a power law extending from a minimum (fixed for all the models $a_{\text{min}} = 0.05$ µm) to a maximum size (listed in Table 1). From these models, we produced high resolution Spitzer spectra, and we extract the water blend fluxes at 15.17, 17.22, and 29.85 µm by adopting the same procedure as described in Pontoppidan et al. (2010a). Finally we also computed the peak strength of the 10 µm silicate feature using Eq. (1).

Figure 2 shows that these two spectral features are emitted from the same region in our standard T Tauri model, and so they arise under the same physical and thermal conditions. Hence, we consider the 10 µm peak strength as an indicator of the continuum opacity in the 10–20 µm water emitting region in disks. The 29.85 µm blend is emitted from larger radii compared to the silicate feature, but there is a partial overlap and so the idea also holds for this blend.

Figure 3 describes the results from four different series of models. The first two series we explored (1 and 2 in Table 1) directly produce an effect on the abundance of µm-sized grains. Extending the maximum dust size while maintaining constant the dust mass and the power law index of the size distribution reduces the population of small grains. As a consequence the strength of the 10 µm feature becomes weaker. Reducing the value of the dust size power law distribution index has the effect of putting more of the dust mass into large particles, and this again reduces the population of small grains. Finally, the effect of changing the gas mass (series 3) is more indirect. It is related to the radial temperature profile due to the presence or absence of large grains in the upper disk layers. If $M_{\text{gas}}$ is low, big grains settle to the midplane, and the small grains in the upper layers are more exposed to the stellar irradiation, due to the partially reduced opacity. Our models show clearly that for a fixed dust composition, changing any of the individual disk properties (1, 2, 3 in Table 1), water blend fluxes anti-corrrelate with the 10 µm silicate peak flux. Instead, models with different luminosities of the central star (series 4) show simultaneously stronger mid-IR water and silicate feature with increasing stellar luminosity (Fig. 3).

If we analyze our models with different $M_{\text{gas}}$, we find a sharp transition at our canonical model ($M_{\text{gas}} = 0.01 M_\odot$; Fig. 3). Models with larger gas mass, show stronger mid-IR water lines at fixed 10 µm peak strength and the blend emitting regions are moved outward by up to 1 au and slightly upward with respect to the 10 µm silicate emitting region in the disk. Models below a gas mass of 0.001 $M_\odot$ show no detectable mid-IR water lines (now emitted inward of 0.2 au) and a stronger 10 µm peak. This is due to the strong settling (because of the lack of gas support), that reduces the number of larger grains in the upper layers. In our prescription for the dust settling (Dubrulle et al. 1995), the dust vertical scale height depends on the gas density. In the inner disk, grains are always unsettled in models with a significant amount of gas mass ($M_{\text{gas}} \geq 0.01 M_\odot$). Only in cases of very low gas mass does the settling become important even in the inner disk. In this case, the emission at 10 µm becomes purely driven by small grains, which produce a much stronger emission feature. A similar effect can be obtained in the models by changing the amount of dust in the disk.

Our standard description for the dust opacity is based on interstellar silicates, while our target list suggests that dust
composition is different in protoplanetary disks. To study the effect of a different dust composition, we perform two additional tests on our standard disk model using different opacity functions: fully crystalline dust grains (labeled Forsterite in Fig. 3) and DIANA standard opacities (60\% forsterite, 15\% amorphous carbon, 25\% vacuum; labeled DIANA in Fig. 3, details can be found in Min et al. 2016). The two different opacity functions produce a very similar shape of the 10 \mu m feature, suggesting that the crystallinity degree alone is not able to reproduce the most extreme observations of peak strength in our sample. The increased opacity of the DIANA standard case suppresses mid-IR water line strength by about a factor of two.

Given that our physical settling prescription is not able to affect the inner disk, we performed an additional test using a parametrized prescription for the settling, in which only dust grains above a certain size are settled, according to

\[ c_s(z, a) = c_{s0}(z) \cdot \min(1, a/a_{\text{settle}})^{-\nu_{\text{settle}}} \]  

where \( c_{s0}(z, a) \) is the sound speed used to compute the scale height of dust of size \( a \) at the height \( z \) above the midplane, \( a_{\text{settle}} \) is the size threshold above which dust starts to be settled, and \( \nu_{\text{settle}} \) is an exponent that modulates the size dependency of vertical settling. In our test we used \( a_{\text{settle}} = 1 \mu m \) and a very extreme value for \( \nu_{\text{settle}} \), which is set to 1, four times larger than the value adopted in Kamp et al. (2011). A different settling prescription, which affects even the inner disk, produces peak values of the silicate feature only a factor two stronger, while the mid-IR water line flux is almost unaffected, because smaller grains (main carrier of the continuum opacity), are still up in the disk layers from which the mid-IR water lines are emitted.

4. Mid-infrared water and silicate relation

We decided to plot our available observations for the mid-IR water line fluxes, against the computed 10 \mu m silicate peak strength. Figure 4 shows the ratio of water blend to continuum flux, versus the 10 \mu m silicate feature peak strength. Diamonds are targets with crystalline dust features (\( F_{11.3}/F_{13} > 0.71 \)), crosses are for the amorphous grains. The color coding is based on the ratio \( F_{10}/F_{13} \) reported in Oliveira et al. (2010). Magenta objects are flat disks (ratio below 1.5), cyan are flared objects, yellow are cold disks and brown are edge-on targets (ratio above 15). Black targets are the ones for which this ratio is not available. Arrows indicate upper limit measurements. The shaded pink boxes encircle the area covered in all of our models.
The existence of two distinct groups of objects with different mid-IR Spitzer spectra, and it prevents us from drawing clear conclusions regarding correlations in the data. Due to the more balanced distribution of the number of targets with amorphous (10 objects) and crystalline (23 objects) dust grains, we use a basic statistical test to investigate the existence of two distinct groups of objects with different mid-IR water line fluxes and silicate feature strength. We perform a Kolmogorov-Smirnov analysis, an Anderson-Darling test, and a Mantel-Haenszel statistical test (for data with upper limits), using either R code\(^4\) or python\(^5\). According to the results from these tests, we find that the 10 \(\mu\)m peaks do not pertain to the same distributions, but can be statistically classified in the groups of amorphous and crystalline. However, the water line fluxes observed in disks with both types of dust grains pertain to the same distribution (Table 2). This result suggests that different levels of 10 \(\mu\)m peak strength (and so the crystallinity of dust) are not behind the differences in water blend strength. We can conclude from the Kolmogorov-Smirnov and the Mantel-Haenszel statistics that water blend fluxes at this wavelength are clearly unaffected by 10 \(\mu\)m peak strength. Because the distributions of water emission for amorphous and crystalline grains seem to be drawn from the same distribution indicates that the two observables are independent (water line fluxes and crystallinity). Since we took the 10 \(\mu\)m peak strength as a proxy for the local dust opacity in the water emitting region, we tentatively conclude that opacity does not directly suppress the mid-IR flux.

### 5. Comparison between observations and models

Our model series 2 and 3 clearly predict an anticorrelation between the strength of the 10 \(\mu\)m silicate feature and mid-IR water line fluxes; however, this is not observed in our data sample. Possible reasons for the apparent non-correlation are the complexity of individual objects, that can be described only by a proper combination of our model series parameters. Also, our sample is very limited, and additional observations should be included to enlarge the sample by at least a factor of 3. This implies getting future spectra from JWST/MIRI (5–28 \(\mu\)m) with greater sensitivity and spatial resolution in order to improve the statistics and in order to allow the construction of a more homogeneous sample, e.g., focus on single spectral type, same disk mass. Considering purely the observations, we can only confirm the presence of two distinct populations in which disks with crystalline dust have peak strengths lower than 1.1.

The range of mid-IR water line fluxes covered by the models overlaps well with the observations, but this is not the case for the 10 \(\mu\)m silicate feature strength. Our series of models underestimate the value of the 10 \(\mu\)m peak strength, which can be up to 3 in the observations. The models able to produce strongest peak values have very steep dust size power law distributions and/or very low gas content. Different opacity functions, using different degrees of crystallization, are not enough to boost the peak strength up to the extreme observations we have. As discussed in Sect. 3, the more physical settling prescription does not allow dust to settle in the inner disk and hence does not cover the high end of observed silicate peak strength (series 3). By adopting an alternative settling prescription that forces dust above a certain size threshold to settle, we produce a greater peak strength for our standard model. This could indicate the presence of strong dust settling in certain disks that is beyond the physical description provided by Dubrulle et al. (1995).

Objects with very strong 10 \(\mu\)m peaks show systematically lower mid-IR water line fluxes; however, there are very few objects with such high silicate peaks limiting our statistics. According to our model results trend, these targets could have a lower gas mass or a particularly high dust content in the innermost disk regions where planet formation occurs. Disks in which planet formation happens can also experience amorphization of dust grains (Watson et al. 2009). This is consistent with the fact that in our data sample, disks with amorphous dust grains have stronger 10 \(\mu\)m peak strength.

Currently, ALMA high spatial resolution observations could investigate whether some of the disks with strong water emission are indeed dust depleted in the inner 10 au.

#### 6. Conclusions

Some of our model series (1, 2, 3, 4) suggest the presence of a regular trend between the strength of the 10 \(\mu\)m silicate dust feature and the mid-IR water blend fluxes. This is directly related to changing dust opacity. A stronger silicate feature is produced by disk properties such as very small dust grains, very steep power law dust size distribution, or very low gas mass. It is an indicator of larger continuum opacity and leads to weaker mid-IR water lines. Dust grains and water both behave in the same manner with respect to the stellar bolometric luminosity (series 5) since both gas and (in particular) dust get warmer.

Observational samples are likely more heterogeneous than what our models currently describe. Disks around T Tauri stars show mainly processed and more crystalline dust, while our modeling is performed with ISM dust (mainly amorphous). The two alternative cases of dust opacity function that we explored cannot explain observed peak strength greater than 1. A test performed with a parametric description of settling shows that our models systematically shift to a peak strength larger by about 0.2 if the inner disk would be settled.

Observations are consistent with relatively flared disks around T Tauri stars and crystalline dust features. From statistical tests, we found that the peak strength is different in disks with amorphous and crystalline grains. We also found that the water line fluxes in the two samples of amorphous and crystalline silicate disks are indistinguishable. This suggests that dust opacity due to the different composition does not drive the difference in mid-IR water fluxes. The independent behavior of these two observables and the results from models of extremely settled disks provide an alternative explanation, namely that some disks have an inner ring within 10 au enhanced in dust or depleted in gas that is experiencing strong settling. High spatial
