Chapter 3

Heightened Attentional Capture by Visual Food Stimuli in Anorexia Nervosa

**ABSTRACT**

The present study was designed to test the hypothesis that anorexia nervosa (AN) patients are relatively insensitive to the attentional capture of visual food stimuli. Attentional avoidance of food might help AN patients to prevent more elaborate processing of food stimuli and the subsequent generation of craving, which might enable AN patients to maintain their strict diet. Participants were 66 restrictive AN spectrum patients and 55 healthy controls. A single-target rapid serial visual presentation (RSVP) task was used with food and disorder-neutral cues as critical distracter stimuli and disorder-neutral pictures as target stimuli. AN spectrum patients showed diminished task performance when visual food cues were presented in close temporal proximity of the to-be-identified-target. In contrast to our hypothesis, results indicate that food cues automatically capture AN spectrum patients’ attention. One explanation could be that the enhanced attentional capture of food cues in AN is driven by the relatively high threat value of food items in AN. Implications and suggestions for future research are discussed.
INTRODUCTION

Anorexia nervosa (AN) is a mental disorder characterized by a fear of gaining weight despite existing underweight. According to the cognitive behavioural theory of eating disorders, the overevaluation of control over eating, shape and weight is of primary importance in maintaining the disorder (Fairburn, Cooper, Shafran, & Wilson, 2008). In line with this, it has been argued that people with AN are characterized by dysfunctional self-schemata related to body size that are reinforced by functionally related information processing biases such as attentional bias (Williamson, White, York-Crowe, & Stewart, 2004). For instance, when walking past a mirror, the attention of a person with AN might be automatically captured by disliked body parts (Glashouwer, Jonker, Thomassen, & de Jong, 2016).

Also attention to food stimuli might be biased. Experimental studies have found that when hungry, people typically show a heightened attentional bias towards food cues as indexed by both color-naming interference effects in a modified Stroop task using food versus nonfood words (Lavy & van den Hout, 1993) and automatic spatial orientation towards food stimuli in a visual probe task (Nijs et al., 2010). Such heightened attention for food cues has been argued to enhance craving, which in turn may promote further the attentional bias for food cues. Thus people may enter an attentional bias-craving cycle that eventually lowers the threshold for actual food-intake (cf. Franken, 2003).

It might, however, be that after prolonged and repeated starvation food loses its motivational salience (e.g., Veenstra & de Jong, 2011) and thereby also its attention grabbing power. If so, this may help prevent AN patients to enter this attentional bias-craving cycle and thus help them in persisting their restrictive food intake. In line with this, previous research using a free viewing task involving food stimuli found evidence for attentional avoidance of food in AN patients (Giel et al., 2011). In this task, picture pairs (food/disorder neutral) appeared on the computer screen. By means of eye-tracking methodology it was shown that AN patients spent less time looking at food pictures than comparison participants without an eating disorder. Conceptually similar results (avoidance of high-caloric food) were found in a study using a pictorial exogenous cueing task (ECT) in AN patients (Veenstra & de Jong, 2012). The ECT is a reaction time (RT)- based spatial attention task in which participants are asked to detect a visual target presented at a left or right peripheral location. In this study, the target was preceded by a task-irrelevant picture (food or disorder neutral) that in half of the trials validly cued the target’s spatial location, whereas in the other half of the trials, the preceding stimulus was presented at the opposite spatial location of the target and thus invalidly cued the target’s location. In line with previous research using the ECT, participants were generally faster on validly than invalidly cued trials. Yet, specifically when targets were preceded by pictures displaying high-caloric food items there was no difference in participants’ response time between validly and invalidly cued trials. The finding that participants were not relatively fast on valid trials when preceded by pictures of high-caloric food, can be interpreted as a tendency to direct attention away from these food stimuli.
There is, however, also evidence that points in the opposite direction. A study using a visual dot probe task with women with various types of eating disorders found that patients exhibited attentional avoidance of pictures of low-caloric eating situations, but an approach bias with regard to pictures displaying high-caloric food situations (Shafran, Lee, Cooper, Palmer, & Fairburn, 2007). Also such visual probe task is a RT-based measure in which participants have to respond to a target (the probe), that is preceded by a task-irrelevant stimulus. A critical difference with the ECT is that in the visual probe task pairs of task-irrelevant stimuli are presented. In this particular study, these pairs always consisted of a nonfood and a food picture, and probes were equally often presented at the location of the preceding food as of the preceding nonfood stimulus. The tendency to direct attention away from food and/or towards nonfood stimuli (attentional avoidance) would result in relatively slow responses on trials for which the probe was presented at the same location as the preceding food stimulus as compared to trials for which the probe was presented at the opposite location of the preceding food stimulus (i.e., at the location of the nonfood stimulus). Finally, a previous study using a pictorial visual search task found increased instead of reduced distraction by high-caloric food cues in eating disorder patients compared to healthy controls (Smeets, Roefs, van Furth, & Jansen, 2008). In this task, participants were instructed to detect a neutral target word among either disorder-relevant or neutral distractor words. Slower RT’s on trials with disorder-relevant than on trials with neutral distractors, indicated increased distraction by disorder-relevant words in eating disorder patients. No evidence was found for speeded detection of high-caloric food words within an array of neutral distractor pictures. Thus, overall, the existing literature does not provide a straightforward outcome.

There are several explanations for these mixed results. First, these studies used different paradigms (dot probe, ECT, visual search task, and free viewing task), and some studies (Shafran et al., 2007; Smeets et al., 2008) did not only include AN patients but also patients with bulimia nervosa (BN), binge eating disorder (BED), or eating disorder not otherwise specified (EDNOS). The eating pattern of both BN and BED patients is characterized by periods of loss of control over eating. These patients might therefore show different biases than women with AN, and this might have contributed to the finding that specifically the studies with mixed patient groups found evidence for an attentional bias toward food and distraction by food stimuli, whereas the studies with exclusively AN patients found attentional avoidance of food cues.

Secondly, all paradigms that were used in these earlier studies focused on the spatial dimension of attentional bias: the tendency to direct the visual attention towards (or away from) specific cues. Attention is, however, not only distributed over space but also over time. The visual world is bursting with information, and stimuli continually compete for a perceiver’s attention: Stimuli that win often reach awareness, whereas those that lose frequently go unnoticed (Most et al., 2007). Little is known about the consequences of continued attention for food-related information for the processing of other (concurrently or subsequently appearing) information. Once a food stimulus has captured attention, it may be preferentially processed and granted prioritized access to limited cognitive
Heightened Attentional Capture by Visual Food Stimuli in Anorexia Nervosa

resources (cf. Koster et al., 2009). Such privileged access may not only prevent new information from entering working memory but also provide the opportunity for more elaborate processing of the food stimulus, which in turn may promote craving and actual approach behaviour.

A task often used to measure the temporal dynamics of attention is the Rapid Serial Visual Presentation (RSVP) task (Raymond et al., 1992). In the single-target version of this task, a target that is preceded by a distractor has to be identified in a stream of stimuli (e.g., landscapes) that is presented in the centre of participants' attention (e.g., Most et al., 2005). These stimuli are presented in quick succession (e.g., 118 ms/stimulus) without interstimulus interval. The time window between the distractor and the target can be manipulated by adding more or fewer filler stimuli between the distractor and the target. A salient distractor can prevent the target identification if it is presented shortly before the target, even when the distractor is task-irrelevant and can be best ignored for optimal task performance. Missing the target is usually most likely to occur in the shorter time lags.

Previous RSVP studies in the context of eating disorder symptoms showed that motivational salience is an important factor in (temporal) attentional bias. Accordingly, a study comparing hungry and satiated participants showed that specifically in hungry participants, task performance was hampered when a food-distractor was presented in close temporal proximity to the target (Piech et al., 2009). Most important for the current context, it was found that this food-based temporal attentional bias is also associated with individual differences in eating behaviour tendencies. More specifically, it was found that food-distractors resulted in stronger temporal attentional bias (as indexed by hampered target identification) for restrained than for unrestrained eaters (Neimeijer, de Jong, & Roefs, 2013). Such nonintentional (bottom-up) tendency to prioritize the processing of food cues may help explain why restrained eaters fail so often despite their strong intention to lose weight. In line with this, it was found that specifically for binge eaters, food stimuli were relatively often accurately identified when presented in the ‘attentional blink,’ the period where information is usually missed, suggesting that food stimuli received processing priority (Schmitz, Naumann, Biehl, & Svaldi, 2015). This might enhance the chance that food elicits craving with a binge as a result.

Together, the available evidence in the context of studies that used the RSVP suggests that people who often fail in regulating their food intake (e.g., restrained eaters, patients with BED) show a preferential processing of food stimuli that interferes with their current goals. Perhaps, then, in contrast with hungry people, restrained eaters, and patients with BED, AN patients might be very efficient in preventing more elaborate processing of food stimuli and subsequent craving. If so, this would help AN patients to persist in their diet-goal. Therefore, the present study was designed to test the hypothesis that AN patients are relatively insensitive to the attentional capture of food stimuli and therefore show diminished attentional distraction by visual food cues within the context of a single-target RSVP.
METHOD
Participants
Participants were treatment-seeking female adolescents who were admitted to the Centre for Eating Disorders of Accare Child and Adolescent Psychiatry (Smilde, the Netherlands). For this study, we selected a group of restricting eaters by including a group of broadly defined AN patients \( n = 66 \), using the Eating Disorder Examination (EDE; Bryant-Waugh, Cooper, Taylor, & Lask, 1996; Dutch version: Decaluwe & Braet, 1999). Next to patients who met all of the DSM-IV (American Psychiatric Association, 1994) criteria of the restrictive type of AN \( n = 33 \), we included patients who met most but not all criteria, that is, patients with menses \( n = 5 \), with only light underweight (1-15%; \( n = 16 \)), patients who were nonfat phobic AN \( n = 2 \), and other partial AN (meeting two of four criteria, \( n = 10 \)) (cf. Thomas, Vartanian, & Brownell, 2009). Age ranged from 12 to 23. For the comparison group, we selected symptom-free female adolescents \( n = 55 \) within the same age range from secondary schools in Groningen. Educational level was determined as high or low within the Dutch system. The percentage highly educated participants in the patient and control group was 58 and 69, respectively, and this did not differ between groups, \( \chi^2 (1, N = 119) = 0.09, p = .77 \).

Materials
RSVP
The RSVP was programmed in E-prime 2.0 (Schneider et al., 2002) administered on a laptop. A single-target version of the task was designed with food-related and disorder-neutral (control) distractors (Neimeijer et al., 2013). Every trial consisted of a stream of pictures that were presented for 118 ms without interstimulus interval. Each stream contained one distractor and one neutral target stimulus. Target pictures had a 10-pixel blue frame, while all other stimuli had a 10 pixel black frame. The number of pictures within a particular stream (10-19 pictures) depended on the position of the distractor and the number of stimuli between distractor and target (1 or 7) stimulus. The target was always followed by a fixed number of four fillers, to ensure that any differences in results across types of trials could not be attributed to a variable time the final target had to be kept in working memory. The order of the trials, as well as which pictures were paired with which lag, was individually randomized. The distractor was randomly presented on one of three possible positions in the stream (4, 6, 8). The target was randomly presented at Lag 2 or 8 following the distractor. In the present setup there were 2 (type of distractor: food, neutral) × 3 (T1 position: 4, 6, 8) × 2 (lag: 2, 8) = 12 different types of trials, each presented six times. See figure 1 for a visual overview of the task.

Stimuli, measuring 550 × 550 pixels, were photographs: 46 high-caloric food stimuli, 57 disorder-neutral pictures and 75 fillers (landscapes). Food pictures were derived from Istockphoto, whereas disorder-neutral photos were derived from the International Affective Picture System (IAPS). Both types of pictures were previously used in Neimeijer et al. (2013). Disorder-neutral pictures were chosen so that there was great variety and consisted of people, animals, and everyday objects like money, a book, and shoes. Food pictures consisted of a wide range of high-caloric palatable food pictures, like fries, a burger, cake, chocolate, and a pizza.
The RSVP started with a four-trial practice session. Hereafter, a total number of trials were presented in three similar blocks of 24 trials, with a 30-s break between the blocks to reduce the influence of fatigue and problems with participants’ concentration. After each trial, participants were asked to type what they had seen on the picture with the blue frame (targets).

**Questionnaires**

**Eating Disorder Examination Questionnaire (EDE-Q).** The child version of the Eating Disorder Examination Questionnaire (EDE-Q; Fairburn & Beglin, 1994; ChEDE-Q; Decaluwé, 1999) was administered, to allow for a comparison of eating disorder pathology between AN-like patients and healthy controls. The EDE-Q is the questionnaire version of the Eating Disorder Examination interview and consists of four subscales (0 – 6 points): restraint, eating concern, weight concern, and shape concern. The total EDE-Q score provides a global measure of the severity of eating disorder pathology.

**Visual Analogue Scales.** Participants’ craving, liking, and participants’ frequency with which they ate the food items represented on the pictures that were used in the RSVP procedure were assessed on a Visual Analogue Scale (VAS) ranging from 0 (not at all) to 100 (very much/very often). To index craving we asked: “How much do you crave this product at this moment?” Liking of food items of the tasks was assessed by answering the question: “How much do you like this product?” To assess the frequency with which they ate the particular food we asked “How frequently do you eat this product?”

**Hunger Scale.** The Hunger Scale (HS: Grand, 1968) consists of four items (time since last eating, subjective hunger, estimate of the amount of favourite food able to eat, estimate of time until next expected meal) and was administered to control for possible differences in hunger across groups. Since time since last eating is considered the most objective measure of hunger, this variable was used to control for the influence of hunger.

**Procedure**

The study was approved by the Medical Ethical Committee of the University Medical Centre Groningen,
protocol number 2011.193. Before participants were scheduled for the assessment, both patients and their parents gave informed consent. After the RSVP, the VAS, and HS were filled out. Finally, height and weight were measured.

**Data reduction**

After the total experiment was finished, the experimenter checked whether the answers of the participants were correct (excluding typos) and specific. In order to derive a measure for temporal attentional bias, percentage correct identified targets as a function of distractor (food, neutral) and lag (2, 8) was calculated. Percentage underweight was derived from the 50th percentile of height and age.

**RESULTS**

**Group characteristics**

See Table 1 for a description of the participants and statistics of the between-groups tests. In line with the inclusion criteria, AN spectrum patients had a higher percentage underweight and higher EDE-Q scores. AN spectrum patients showed less craving, liking, and frequency of eating the foods, than healthy controls. Furthermore, AN spectrum patients reported longer time since last eating, and a trend significantly longer time until expected next meal, but less subjective hunger, and lower amount of favourite food that could be eaten right now. Eating-disordered patients and healthy controls did not differ with respect to their age.

analysis of variance showed a main effect of lag, $F(1, 119) = 124.31, p < .01, \eta^2_p = .51$. Participants were overall more accurate in identifying targets when presented at lag 8 than at lag 2 following the distractor stimulus. Thus, presenting a task-irrelevant distractor elicited an ‘attentional blink’. Furthermore, there was a main effect of group, $F(1, 119) = 6.03, p = .02, \eta^2_p = .05$, indicating that AN spectrum patients generally showed a lower rate of accurate target identification. There was no main effect of distractor type, $F(1, 119) = 0.99, p = .32, \eta^2_p = < 0.01$, indicating that in general, participants did not have more difficulties identifying a target after a food than after a neutral distractor stimulus. Most relevant for the present context, there was a Distracter type × Group effect, $F(1, 119) = 8.63, p < .01, \eta^2_p = .07$, indicating that there was a difference between the two groups as a function of type of distracter. Independent sample $t$ tests showed that there was no difference between the two groups in percentage correctly identified pictures after a neutral distracter, $t(119) = 1.43, p = .16, d = .26$, but there was a difference in performance on trials with a food distracter, $t(119) = 3.10, p < .01, d = .57$. AN spectrum patients were more distracted by food cues, thereby hampering subsequent target detection. Although the effect seemed most pronounced for lag 2, the Distracter type × Group × Lag interaction was not significant, $F(1, 119) = 2.05, p = .16, \eta^2_p = .02$. The effect remained stable if controlled for hunger (using time since last eating as a covariate), $F(1, 119) = 8.40, p < .01, \eta^2_p = .05$, so the effects cannot be attributed to more hunger in the patient group. See Figure 2 for a visual presentation of the results. In order to further explore the relationship between eating disorder symptoms and RSVP performance, difference scores were calculated (percentage correct identified food pictures minus percentage correct identified neutral pictures) for both lags, thereby

![Figure 2. Percentage correctly identified targets as a function of distracter type.](image-url)
controlling for general RSVP performance. Negative scores indicate an attentional bias for food stimuli. This RSVP difference score for Lag 2 was significantly associated with all EDE-Q subscales: restraint, $r(121) = -.21, p = .02$; eating concerns, $r(121) = -.23, p = .01$; weight concerns, $r(121) = -.19, p = .04$; and shape concerns, $r(121) = -.23, p = .01$, indicating that more severe eating disorder symptoms were associated with a stronger attentional bias. There were no significant correlations between EDE scores and the difference scores for Lag 8, all $r$s$(128) < -.05$, all $p$s $> .60$.

DISCUSSION

The present study was a first attempt to investigate temporal attentional bias for food in AN spectrum patients. The results clearly indicate that in AN spectrum patients target detection is hampered when it is preceded by a food distractor and that more severe eating disorder pathology is associated with a stronger attentional bias for food cues. Thus, in contrast with the hypothesis, AN spectrum patients showed a bottom-up attentional capture by visual food cues that interfered with their current task (i.e., target identification). This is in line with some earlier studies on (spatial) attentional bias that also showed heightened distraction by food stimuli in eating disorder patients (Shafran et al., 2007; Smeets et al., 2008).

The hypothesis that food has lost its attention grabbing power in AN spectrum patients (e.g., through prolonged starvation and repeated exposure to food without consequently eating) is not supported by these findings. In fact, prolonged food deprivation might have led to an even stronger attentional bias for food. The addiction account of attention states that there is a reciprocal relationship between attention for food and craving (Nijs et al., 2010). The current finding that AN spectrum patients show attentional capture by food stimuli might then reflect heightened craving in these patients. Also earlier studies link temporal attentional bias and craving (Piech et al., 2009; Neimeijer, 2013; Schmitz et al., 2015). AN patients show an attentional bias but do not get caught in the attentional bias-craving-eating cycle. This seems to imply that they have high self-regulation skills to resist food-related short-term reinforcement that runs counter to their diet-goal. In other words, it seems that (attentional) avoidance of food cues in AN is not so much sustained by attenuated automatic attentional capture but reflects processes involving more top-down control.

The heightened attentional capture might also be driven by the threat value of food. That is, food cues might not only be salient because of their hedonic value but, especially in AN, also because of their threatening associations with gaining weight and losing control over eating. Indeed, previous research consistently found that negative stimuli (e.g., trauma reminders) can capture and hold attention, as well as hamper ongoing task performance (e.g., Most et al., 2005; Olatunji, Armstrong, McHugo, & Zald, 2013; Verwoerd, Wessel, & de Jong, 2010). When a fear-associated stimulus is detected, processing resources are automatically diverted from less salient cues to these feared stimuli in order to escape the danger as quickly as possible. Hyperattention to feared stimuli can, therefore, facilitate an early escape (Lavy, van den Hout, & Arntz, 1993). Although there was no significant effect for lag in the current study, the effect seemed most prominent when
the distractor was presented in close temporal proximity of the target (Lag 2). The correlational analysis also showed that stronger attentional bias in Lag 2 was associated with more severe eating disorder pathology. This might indicate that there is an initial vigilance for food cues, and that attention bias is ‘recovered’ on the longer lag (see also Most et al., 2005). It could also be that even a subsequent avoidance is shown, a pattern that is also seen in the context of anxious concerns (e.g., Mogg, Bradley, Miles, & Dixon, 2004).

An attentional bias for food in AN might thus reflect fear of gaining weight or losing control over eating and could contribute to dietary restraint and (behavioural) avoidance of food stimuli. It might, however, also be that the threat for AN patients is approaching the food and giving in to the craving they may experience. As earlier described, especially for underweight participants the prolonged food deprivation and the basic organismic need for nutrition might have led to an attentional bias for food, which in turn may lower the threshold for nonintended food consumption. In the meantime, a quick detection of food cues may also help to quickly escape from stimuli or contexts that signal food-intake, thereby supporting their ongoing diet goal.

The current pattern of findings cannot be attributed to a generally worse performance of AN spectrum patients in the RSVP task, because the difference between patients and the control group was restricted to food distracters. Also the presence of hunger does not explain the differences, as the main results remained unaffected when we statistically controlled for hunger. However, it should be mentioned that ongoing food deprivation may not be fully captured by time since last meal or subjective hunger.

AN spectrum patients did also more generally show lower identification rates than healthy controls which may be caused by underweight, as underweight is known to influence cognitive processes as thinking and concentration (Keys, Brožek, Henschel, Mickelsen, & Taylor, 1950). Because restrictive food intake is in particular a feature of the restricting AN, we only included this subtype. Therefore, the results cannot be generalized to all AN patients (i.e., the binge/purging subtype). It seems plausible that binge/purging individuals may show the same pattern of finding, but future research is necessary to test this.

To conclude, in this study temporal attentional bias in a large group of AN spectrum patients was tested. Patients showed heightened distraction by food cues, which might indicate that food cues are highly salient. It remains unclear whether this means that AN spectrum patients do experience automatic craving for food (as an analogue with addiction) or that food has a high threat value (as an analogue with anxiety), or both (when the threat is approaching the food and give in to craving). In addition, an important next question is whether biased attention for food is an epiphenomenon when having eating concerns or has also a causal relationship with these concerns. A first step to examine whether it contributes to the maintenance of the disorder would be to test if the temporal attentional bias would normalize under influence of (successful) treatment and if a (more pronounced) bias predicts worse treatment outcome.
