§Supporting Information

**ABSTRACT:** Xylose isomerase from *Piromyces* sp. E2 (PirXI) can be used to equip *Saccharomyces cerevisiae* with the capacity to ferment xylose to ethanol. The biochemical properties and structure of the enzyme have not been described even though its metal content, catalytic parameters, and expression level are critical for rapid xylose utilization. We have isolated the enzyme after high-level expression in *Escherichia coli*, analyzed the metal dependence of its catalytic properties, and determined 12 crystal structures in the presence of different metals, substrates, and substrate analogues. The activity assays revealed that various bivalent metals can activate PirXI for xylose isomerization. Among these metals, Mn2+ is the most favorable for catalytic activity. Furthermore, the enzyme shows the highest affinity for Mn2+, which was established by measuring the activation constants (K_{act}) for different metals. Metal analysis of the purified enzyme showed that *in vivo* the enzyme binds a mixture of metals that is determined by metal availability as well as affinity, indicating that the native metal composition can influence activity. The crystal structures show the presence of an active site similar to that of other xylose isomerases, with a D-xylose binding site containing two tryptophans and a catalytic histidine, as well as two metal binding sites that are formed by carboxylate groups of conserved aspartates and glutamates. The binding positions and conformations of the metal-coordinating residues varied slightly for different metals, which is hypothesized to contribute to the observed metal dependence of the isomerase activity.

**Cost-effective production of second-generation bioethanol requires maximal utilization of sugars present in cellulosic biomass, because raw materials account for approximately one-third of the overall production cost.** Besides D-glucose, the most abundant monosaccharide in lignocellulose and hemicellulose is D-xylose, and fermentation of xylose along with glucose would significantly increase the total ethanol yield. For such simultaneous fermentation of glucose and xylose, *Saccharomyces cerevisiae* would be a particularly attractive organism as it is an established ethanol producer that is not very vulnerable to inhibitors present in cellulose hydrolysates and shows a relatively high tolerance to extracellular ethanol. However, natural strains of *S. cerevisiae* do not metabolize xylose, because of its inability to convert D-xylose to D-xylulose, an aldose to ketose isomerization reaction. Because D-xylulose can be metabolized, research has been devoted to engineer yeast variants that express a heterologous xylose isomerase for catalyzing this reaction. Alternatively, xylose isomerization can be achieved by incorporating both a xylose reductase and a xylitol dehydrogenase, although this is not preferred because it could cause a cellular cofactor imbalance. Because xylose isomerase requires only metal cofactors, it offers the most attractive solution. Furthermore, the use of an isomerase rather than dehydrogenases prevents the formation of xylitol, which may emerge as an unwanted side product.

Xylose isomerases and related glucose isomerases have been studied for decades because of their application as glucose isomerasers in the production of high-fructose corn syrups from starch hydrolysates. The use of the enzymes in ethanol-producing yeasts has been more recent. Isomerases from different bacterial sources, including *Escherichia coli*, *Actinoplanes missouriensis*, *Streptomyces rubiginosus*, *Bacillus subtilis*, and *Clostridium thermosulfurogenes*, have been tested, but functional expression in *S. cerevisiae* appeared to be problematic. Xylose isomerase from *Thermus thermophilus* was functionally expressed in *S. cerevisiae*, but the enzyme from this thermophilic organism showed very low activity at 30 °C.

The first eukaryotic XI gene that could be expressed well in its active form in *S. cerevisiae* was obtained from the anaerobic fungus *Piromyces* sp. E2 (PirXI), and its expression in an *S.*
cerevisiae enabled the fermentation of xylose to ethanol.\textsuperscript{5,17,18} Although later a few xylose isomerases from other sources were also expressed in \textit{S. cerevisiae},\textsuperscript{3,4,6,19,20} xylose-based growth rates and ethanol production levels do not exceed those found for the \textit{S. cerevisiae} expressing XI from \textit{Piromyces} sp. E2.\textsuperscript{18} A further improved \textit{S. cerevisiae} strain equipped with PirXI indeed showed high ethanol production yields, reaching almost the theoretical level, and the use of xylose isomerase appears to be preferable over the combination of a xylose reductase and a xylitol dehydrogenase allowing isomerization via xylitol.\textsuperscript{10,20}

In spite of these promising achievements, there is significant room to improve the anaerobic metabolism of xylose. Engineering of the strain by overexpressing the non-oxidative pentose phosphate pathway enzymes may enhance the growth rate.\textsuperscript{20,21} Evolutionary optimization can also improve the rate of xylose consumption.\textsuperscript{52,23} In such improved \textit{S. cerevisiae} strains, a very high expression level of PirXI is still required for growth on xylose, especially for anaerobic metabolism, and in such evolved strains, PirXI may be the major intracellular protein (unpublished data). This must be an energetic burden to the cells and also indicates that xylose isomerization still is the rate-limiting step in engineered strains that have lower expression levels of xylose isomerase. No detectable accumulation of the product xylulose in an anaerobic culture of an engineered and PirXI-expressing strain growing on xylose was found, further suggesting that PirXI activity is limiting xylose metabolism.\textsuperscript{21} Therefore, engineering of PirXI to enhance its activity will further improve xylose utilization. A directed evolution study using error-prone polymerase chain reaction showed that a more active xylose isomerase could enhance the growth of \textit{S. cerevisiae} on xylose.\textsuperscript{20} Further progress and more focused engineering of the enzyme are hampered by the lack of a description of the biochemical properties of PirXI and the absence of structural information.

Xylose isomerases are tetrameric enzymes that require two bivalent metals to catalyze the isomerization of the aldose D-xylose to the ketose D-xylulose (Figure 1). One of them is often described as the structural metal as it is involved in the proper binding of the substrate and the other as the catalytic metal as it is critical for the isomerization reaction.\textsuperscript{27} The activity of xylose isomerase is reported to be influenced by the type of metal that is bound. For example, Mg\textsuperscript{2+}, Co\textsuperscript{2+}, and Mn\textsuperscript{2+} are known to be activators, and Ni\textsuperscript{2+}, Cu\textsuperscript{2+}, Zn\textsuperscript{2+}, Ca\textsuperscript{2+}, and Fe\textsuperscript{2+} mostly act as inhibitors.\textsuperscript{26,28–30} Although the active sites of xylose isomerases are highly conserved, the metal preferences of the enzymes vary. Some XIs seems to be most active with Mg\textsuperscript{2+}, while others show the highest activity with Mn\textsuperscript{2+}.\textsuperscript{28,31,32} The importance of the metal dependence for \textit{in vivo} conversion of D-xylose was recently discovered in a study showing that mutations influencing metal homeostasis through inactivation of the PMR1 gene increase the relative Mn\textsuperscript{2+} content of \textit{S. cerevisiae} cells and of the expressed PirXI.\textsuperscript{33}

XIs can be divided into two structural types, i.e., class I and class II enzymes. The major difference between the two classes is an N-terminal extension in class II xylose isomerases. From sequence analysis, the PirXI enzyme explored here appears to be a class II xylose isomerase. Currently, only a few class II XI structures are available,\textsuperscript{34} and these have no bound substrates, unlike structures for class I XIs that have been obtained with different ligands.

In this study, we describe the catalytic properties of PirXI expressed in \textit{E. coli}. We also examined the metal specificity of the enzyme by measuring catalytic activities and affinities with a range of different metals that might be present in the cytosol of \textit{S. cerevisiae} during the fermentation process. Furthermore, we report several structures of the class II XI from \textit{Piromyces}, determined by X-ray crystallography, with various combinations of metals (Mg\textsuperscript{2+}, Mn\textsuperscript{2+}, Co\textsuperscript{2+}, Fe\textsuperscript{2+}, Ca\textsuperscript{2+}, Ni\textsuperscript{2+}, and Cd\textsuperscript{2+}) and substrate (xylose), product (xylulose), or inhibitor (xylitol or sorbitol). The results indicate that small differences in metal–protein interactions influence the position and reactivity of bound metals.

Figure 1. Mechanism of conversion D-xylose to D-xylulose.\textsuperscript{25,26} Linearization of D-xylose catalyzed by His102/Asp105 is followed by movement of the catalytic metal from position M2a to position M2b, where it coordinates with O1 and O2 of the sugar. A proton is transferred from O2 to O1, and a hydride shifts from C2 to C1. D-Xylulose is formed by ring closure.
Expression of PirXI in *E. coli*. A synthetic *xylA* gene encoding XI from *Pirromyces* sp. E2 (GenBank accession number AJ244909) was obtained from GenScript USA Inc. (Piscataway, NJ). The sequence was codon-optimized for expression in *E. coli*. The *xylA* gene was cloned into a pBAD/myc-His-derived plasmid (Invitrogen). In this plasmid, the original NdeI sites were replaced and the Ncol site was replaced with an NdeI site. The *xylA* gene was cloned using NdeI and HindIII sites with insertion of a stop codon at the end of the *xylA* coding sequence. The obtained pBAD-PirXI plasmid was transformed into *E. coli* Top10 (Invitrogen) or NEB 10-β (New England Biolabs). The sequence of the plasmid was verified by sequencing.

For expression of XI, *E. coli* Top10 cells or NEB 10-β cells harboring the pBAD-PirXI plasmid were cultivated in TB medium (12 g/L tryptone, 24 g/L yeast extract, 5 mM/L glycerol, 2.31 g/L KH2PO4, and 16.43 g/L K2HPO4·3H2O) supplemented with 50 μg mL⁻¹ ampicillin and 0.2% (w/v) L-arabinose for 16 h at 37 °C. The cells were harvested by centrifugation, washed with 20 mM Tris·HCl (pH 8.5), and directly used for enzyme purification or stored at -20 °C until further use.

**Purification of XI Overexpressed in *E. coli***. The cells were disrupted by sonication, and cell debris was removed by centrifugation for 45 min at 31000g and 4 °C. The supernatant was applied to a Q-sepharose Fast Flow resin (GE Healthcare) equilibrated with 20 mM Tris·HCl (pH 8.5) in a gravity column and incubated for 30 min at 4 °C. The column was washed with 15 column volumes of 20 mM Tris·HCl (pH 8.5). Then xylose isomerase was eluted from the column using 20 mM Tris·HCl (pH 8.5) containing 100 mM glycerol, 2.31 g/L KH2PO4, and 16.43 g/L K2HPO4·3H2O supplemented with 50 μg mL⁻¹ ampicillin and 0.2% (w/v) L-arabinose for 16 h at 37 °C. The columns were further used for enzyme purification by centrifugation, washed with 20 mM Tris·HCl (pH 8.5), and stored at 4 °C for several weeks.

For long-term storage, the protein was frozen in liquid nitrogen and stored at -80 °C.

**Activity Assays.** Most assays were performed using the enzyme with a controlled metal composition. For this, we first prepared the apoenzyme by buffer exchange with 10 mM EDTA in 10 mM Tris·HCl (pH 8.0) using either dialysis or EconoPac 10-DG desalting columns (Bio-Rad). The samples were incubated with EDTA for 30 min. Subsequently, EDTA was removed by buffer exchange with 10 mM MOPS (pH 7.0).

The activity of this apoXI assayed in the absence of added bivalent metal ions was <0.02 unit/mg.

In most cases, XI activities were measured by a coupled enzyme assay using D-sorbitol dehydrogenase (SDH). D-Xylose formed by XI activity is reduced by SDH to xylitol, which is monitored by following NADH oxidation spectrophotometrically at 340 nm. SDH was obtained from Roche Diagnostics GmbH (Mannheim, Germany). The standard reaction was performed at 30 °C, and the mixtures contained 20 mM MOPS (pH 7.0), 1 mM bivalent metal ions, 150 mM D-xylose, 0.15 mM NADH, and 1 unit/mL SDH. Reactions were initiated by adding 0.05–0.2 μM apoXI. The amount of XI was adjusted so that the ratio of SDH activity to XI activity would be at least 30. In the case of assays in the presence of Co²⁺, the amount of SDH was doubled to balance the inhibitory effect of Co²⁺ ions on SDH activity. The absorbance at 340 nm was followed using a spectrophotometer (Jasco) or a Synergy Mx microtiter plate reader (BioTek Instruments, Inc.). D-Xylose and D-fructose stocks (2 M) were made in Milli-Q water and stored at -20 °C. The measurements were performed in duplicate. One unit of XI activity is defined as the amount of enzyme catalyzing conversion of 1 μmol of D-xylose per minute under the assay conditions.

Kinetic parameters of XI for D-xylose were determined by measuring XI activity with varying D-xylose concentrations in the range of 0.04–1875 mM, depending on the metal cofactor used. For pH profiling of XI activities, different buffers (50 mM) were used to establish pH values: MES for pH 5.5 and 6.0 and MOPS for pH 6.5, 7.0, and 7.5. Activities of the native enzyme isolated from *E. coli* were measured in the presence of 1 mM MgCl₂, using the spectrophotometric assay described above. For determining the apparent metal affinities (K₆ values), the activity of apo-PirXI was measured in the presence of varying metal concentrations (1–4000 μM) using 150 mM xylose as the substrate for Mg²⁺ and Mn²⁺, 1375 mM xylose for Ca²⁺, and 15 mM xylose for Co²⁺. The concentration of the enzyme used was in the range of 0.05–0.2 μM for the reactions with Mg²⁺, Mn²⁺, and Co²⁺ and 0.5–1.0 μM for the reaction with Ca²⁺.

For measuring the activities of PirXI with metal cofactors that are not compatible with the SDH-coupled assay, activities were examined by measuring the formation of D-xylulose from D-xylose by high-performance liquid chromatography (HPLC). Reaction mixtures containing the substrate, PirXI, and 1 mM metal ions in MOPS (pH 7.0) were incubated at 30 °C while being shaken. Reactions were stopped by acidification with HCl and addition of acetonitrile to a final concentration of 80%. Samples were then separated on an XBridge BEH Amide column (4.6 mm × 250 mm, pore size of 130 Å, particle size of 3.5 μm, Waters). Separation conditions were isocratic with 80% acetonitrile and 20% 20 mM MOPS (pH 7.0) and a flow rate of 1 mL/min at 80 °C. The ultraviolet (UV) absorbance at 210 nm was measured for D-xylulose quantification. For measuring XI activity with Fe³⁺, oxygen-limited reaction mixtures were prepared by flushing the reaction components and the mixture with argon. For this, the reaction mixtures were incubated in a 30 °C water bath. During the reaction, the argon was flushed over the surface of the reaction mixture, and for sampling, a syringe was used. The activity of PirXI on glucose was also measured using the HPLC assay as described above. The activities with different concentrations of glucose ranging from 0.1 to 1.5 M were measured in the presence of 1 mM MgCl₂ as the metal cofactor. A refractive index detector was employed for D-fructose quantification.

**Metal Analysis.** XI purified from *E. coli* was lyophilized and analyzed for the presence of calcium, cobalt, copper, iron, magnesium, manganese, and zinc using inductively coupled plasma optical emission atomic spectroscopy on an Optima 7000DV ICP-OES apparatus (PerkinElmer). The measurements were performed in duplicate. Before lyophilization, a molybdenum standard (molybdenum ICP standard Certipur, Merck Millipore) was added to the sample to a final concentration of 5.0 μg/mL.

**Crystallization and Structure Determination.** Initial vapor-diffusion crystallization experiments were performed using a Mosquito crystallization robot (TTP Labtech). In a typical experiment, 0.1 μL of the screening solution was added.

The values represent averages and the mean deviation calculated from two or three replicates. The initial rate at 200 mM substrate was calculated from steady-state parameters. K₅₀ is defined as the metal concentration at which the enzyme activity is half the V₅₀. No activity detected with the HPLC assay described in Materials and Methods.

RESULTS

Expression of PirXI in E. coli and Enzyme Isolation. To overexpress the Pyromyces sp. E2 xylose isomerase (PirXI) in E. coli, a codon-optimized synthetic xylA gene was cloned into the pBAD vector and transformed into E. coli Top10. Overnight cultivation at 37 °C with induction of PirXI by 0.2% arabinose resulted in high levels of soluble PirXI. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) analysis showed that PirXI is the predominant protein in cell lysates, accounting for >50% of the total soluble protein. This allowed purification by a single step of ion-exchange chromatography, which after desalting routinely yielded 300–500 mg of purified xylose isomerase per liter of culture. From this material, the apo-enzyme was prepared by treatment with EDTA to study the metal dependence of the isomerase activity. The purified enzyme was stored at −80 °C for use in further biochemical experiments.

SDS–PAGE showed that the size of the protein monomer is around 50 kDa, which is in good agreement with the calculated size of the protein, 49.5 kDa. Analytical size exclusion chromatography revealed a molecular weight of ~200 kDa for the native PirXI, showing that the enzyme is a tetramer.

Metal Dependence of PirXI Activity. Because xylose and glucose isomerases require bivalent metals for activity, and the type of metal that is bound may influence the activity, we...
examined the effect of different metal ions on the activity of 
PirXI. Kinetic parameters of apo-PirXI in the presence of Mg$^{2+}$,
Mn$^{2+}$, Co$^{2+}$, or Ca$^{2+}$ were measured using the SDH-coupled
assay as described in Materials and Methods.

PirXI showed good activity in the presence of Mn$^{2+}$, Co$^{2+}$, and
Mn$^{2+}$ (Table 2). Among these metals, the highest activity ($k_{cat}$)
of the enzyme was obtained with Mn$^{2+}$, followed by Mg$^{2+}$
and Co$^{2+}$. The substrate affinity with xylose ($K_M$), on the other
hand, was best in the presence of Co$^{2+}$, which gave a $K_M$ of 0.3
mM and also the highest catalytic efficiency ($k_{cat}/K_M$). In the
presence of Mn$^{2+}$ or Mg$^{2+}$, the $K_M$ of the enzyme was 15–20-
fold higher. This metal preference of PirXI is similar to what
was described for other class II XIs, which were reported to be
most active with Mn$^{2+}$, whereas the class I enzymes are most
active with Mg$^{2+}$.

When Ca$^{2+}$ was added as the metal cofactor of PirXI, the enzyme
showed activity, although it was lower than with the other metals mentioned above. A striking
observation was the extremely low xylose affinity ($K_M$ ~ 2 M)
in the presence of Ca$^{2+}$, resulting in a poor catalytic efficiency ($k_{cat}/K_M = 0.2$ s$^{-1}$ M$^{-1}$). The low substrate affinity suggests that the
Ca$^{2+}$-containing enzyme will provide a negligible contribution to in vivo conversion of xylose by PirXI.

Further assays for determining the metal dependence of
PirXI activity were performed using an HPLC assay for
measuring xylulose formation because the SDH-coupled assay
is not compatible with the presence of Zn$^{2+}$, Fe$^{2+}$, Cd$^{2+}$, Ni$^{2+}$,
and Al$^{3+}$ as these metals inhibit SDH activity. Furthermore, in
the case of Fe$^{2+}$-dependent activity, the reactions were performed under reduced oxygen conditions to prevent
oxidation of Fe$^{2+}$ to Fe$^{3+}$. In these experiments, we measured initial conversion rates (units per milligram) of xylose that was
added to a final concentration of 200 mM. PirXI showed activity in d-xylose isomerization in the presence of Zn$^{2+}$, Fe$^{2+}$, Cd$^{2+}$,
and Ca$^{2+}$. The rate of xylulose conversion with Zn$^{2+}$ was almost
half of that measured with Mg$^{2+}$. Furthermore, Fe$^{2+}$ gave
moderate activity compared to activities with other metals.
Unexpectedly, the enzyme also showed some activity in the
presence of Cd$^{2+}$, which was reported to be an inhibitor of another xylose isomerase. However, the activity (0.2 unit/mg) was very low. No detectable amount of xylulose (<50 μM)
was found with Ni$^{2+}$ or Al$^{3+}$ as the metal cofactor upon measurement after incubation of the reaction mixture for 2 h.

**Metal Affinity of PirXI.** The results described above show that PirXI can be activated by a range of different bivalent metal
ions. Obviously, the activity in vivo will also be determined by
metal affinity and metal availability in the cytoplasmic
environment. Therefore, we investigated the activity of PirXI
on xylose in the presence of different concentrations of divalent 
metals and determined half-saturation constants for activation of the enzyme ($K_M$ values (Table 2)).

Of the metals tested (Mg$^{2+}$, Mn$^{2+}$, Co$^{2+}$, and Ca$^{2+}$), the
highest affinity was found with Mn$^{2+}$. The enzyme also showed
a high affinity for cobalt, but the affinities for Mg$^{2+}$ and Ca$^{2+}$
were 70- and 100-fold lower compared to that of Mn$^{2+}$,
respectively.

Analysis by inductively coupled plasma atomic emission
spectroscopy showed that the main divalent metal in native PirXI isolated from *E. coli* is Mg$^{2+}$, which accounted for
approximately half of the total metal content (Table 3). Ca$^{2+}$
and Fe$^{2+}$ were also detected, whereas the enzyme contained
only a few percent (moles per mole) of Mn$^{2+}$ and Zn$^{2+}$. This
indicates that Mg$^{2+}$ would strongly influence the in vivo enzyme activity in *E. coli*, while Mn$^{2+}$ ions, which are most beneficial for
activity, would have little influence. In agreement with this, the
native enzyme isolated from *E. coli* showed activity similar to
that of the enzyme reconstituted with Mg$^{2+}$ or even slightly
lower activity, probably due to the effect of Ca$^{2+}$ and Fe$^{2+}$. The metal composition and the activity of the enzyme are slightly
different from one batch of isolated enzyme to another (WT1–
WT3). The data also suggest that intracellular metal availability
influences the metal composition of the enzyme (Mg > Ca > 
Mn > Co) as much as the relative affinities (Mn > Co > Mg > 
Cd). Accordingly, in *vivo*, the enzyme may have suboptimal activity because of the level and type of metal binding. Recently,
Verhoeven et al. showed that the increase in the intracellular 
Mn$^{2+}$ level improved the growth of *S. cerevisiae* on xylose by
enhancing PirXI activity.

**pH Dependence of PirXI Activity.** The cytosolic pH of *S. cerevisiae* during the fermentation process is <7.0, possibly
because of the influence of acidic lignocellulose hydrolysate.52 We measured the activity of PirXI at different pH values ranging from 5.5 to 7.5 in the presence of Mg$^{2+}$, Mn$^{2+}$,
Ca$^{2+}$, or Co$^{2+}$ (Figure 2). Because of the high $K_M$ of the enzyme in the presence of Ca$^{2+}$, the activity was measured at a higher 
xylose concentration, 1 M instead of 150 mM. With Mg$^{2+}$,
Mn$^{2+}$, and Ca$^{2+}$, the results show a similar broad pH profile,
with the highest activity at pH 7.5, and a significantly reduced activity at pH 6.5. The lower activity at low pH was more pronounced for Mg$^{2+}$, the quantitatively most important cation in the non-reconstituted enzyme. The activity of the Co$^{2+}$-
reconstituted PirXI was much less dependent on pH in the
range of 5.5–7.5.

**Crystal Structure of PirXI.** PirXI isolated from *E. coli*
readily crystallized from PEG 3350 at pH 7. The structure was
determined by using X-ray diffraction and molecular replace-
ment and was refined against 1.8 Å resolution diffraction data
to an $R$ factor of 0.116 ($R_{free} = 0.148$) with good
stereochemistry (Table 1 and Figure 3A). The P1 unit cell contains four monomers that form a 92 Å × 77 Å × 77 Å
tetramer, having noncrystallographic 222 symmetry. The four subunits have root-mean-square deviation (rmsd) values of
0.11–0.16 Å on Ca atoms. Each PirXI subunit comprises two structural domains, a larger catalytic domain (residues 1–377)
with a distorted ($β/α$)$_8$-barrel (TIM-barrel) fold and a C-terminal domain (residues 378–437) forming an extended tail containing three $α$-helices.

With other class II xylose isomerases with PDB entries of
4XKM (*B. thetaiotaomicron*), 1A0C (*T. thermosulfurigenes*),
1A0D (*B. stearothermophilus*), and 1A0E (*T. neapolitana*),
rmsd values are 0.4 Å on 435 Ca atoms, 1.2 Å on 430 Ca
atoms, 1.1 Å on 425 Ca atoms, and 1.2 Å on 422 Ca atoms,
respectively, while with the well-studied St. rubiginosus class I enzyme, the rmsd is 2.0 Å on 352 C\(_\alpha\) atoms and 27% sequence identity. Major differences between the class I St. rubiginosus XI and the class II PirXI are the presence in the latter enzyme of an N-terminal extension of \(\sim 33\) residues, an N-terminal addition of \(\alpha\)-helix 1, and a larger loop before \(\alpha\)-helix 2. Furthermore, the C-terminal regions deviate the most with low identity, except for the ultimate \(\alpha\)-helix 12 (Figure S1).

A pair of subunits forms the "yin-yang" dimer with rotational symmetry by contacts of the catalytic domain of subunit A interacting with the C-terminal tail of subunit B, while the core of subunit B is interacting with the C-terminal tail of subunit A (Figure 3B). The other dimer pairs are called the "butterfly" dimer (Figure 3C) and the "diagonal" dimer (Figure 3D). The tetramer has a surface area of 53920 Å\(^2\), of which 36840 Å\(^2\) is buried. Each subunit has a total solvent accessible surface area of 21100 Å\(^2\), of which 8110 Å\(^2\) is buried. The interactions in the yin-yang and diagonal dimers are mainly present between the N- and C-terminal tails of the subunits, while the butterfly dimer has interactions between the cores of the subunits.

The sizes of the interface areas are similar in other class II xylose isomerases for which the structures have been determined (PDB entries 4XKM, 1A0C, 1A0D, and 1A0E) (Table 4). However, the xylose isomerase from St. rubiginosus, the most studied class I XI in the PDB, has a larger interface for the yin-yang dimer (4670 Å\(^2\)) and a smaller interface for the diagonal dimer (1460 Å\(^2\)) as it is missing the N-terminal extension of the class II enzymes. Class II enzymes, having larger dimer interfaces and interactions with the other subunit, should be regarded as tetramers unlike class I enzymes, which are usually described as a dimer of dimers.\(^{34}\)

**Active Site Structure.** The active sites of the PirXI subunits are located on the C-terminal end of the \((\beta/\alpha)_8\)-barrel of the core domain. The active sites are 36 Å apart in yin-yang, 31 Å apart in butterfly, and 39 Å apart in diagonal dimers. Residues from the loops following the \(\beta\)-strands shape the active site. The active site pocket is lined by the side chain indole groups from Trp50 and Trp189 that are situated 8.8 Å from each other forming a cassette for sugar binding (Figure 4A,B). Other hydrophobic residues surrounding the substrate binding site are Phe61 from another subunit of the butterfly dimer, Phe146 and Trp140.

In the crystals obtained with native PirXI isolated from E. coli, only the position of the structural metal (M1) in the active site is occupied. Residues Glu233, Glu269, Asp297, and Asp340...
bind M1 with octahedral geometry (Figure 4A). The nature of the metal ion was unclear from the structure as a mixture of different metals may bind. The observed metal−donor distances were 2.1−2.2 Å. The optimal distance for Ca2+ is 2.36 Å, for Mg2+ 2.26 Å, and for Fe2+ 2.01 Å to monodentate Asp or Glu.54 An anomalous difference map showed a peak at the M1 position indicating a bound Ca2+ or Fe2+ ion. Refining with a Ca2+ ion with full occupancy showed residual Fo−Fc density and distances that were too short, while refining with 100% Fe2+ showed deficit density and distances that were too long. Therefore, M1 was refined to occupancies of 0.4, 0.35, and 0.25 for Ca, Mg, and Fe, respectively, which gave a flat Fo−Fc map after refinement. The ambiguous metal ion content has also been observed in native crystals of St. rubiginosus with 0.6 equiv of Mn, <0.6 equiv of Mg, and <0.1 equiv of Co per monomer.55 In this PirXI structure, a glycerol molecule from the cryoprotectant is bound in the active site to the metal ion with a Me−O2 distance of 2.3 Å and a Me−O3 distance of 2.4 Å. Glycerol, acting as a sugar mimic, is often found in active sites of carbohydrate-converting enzymes.56

The crystal structure obtained with EDTA-treated XI is highly similar to the native structure with an rmsd of 0.1 Å. As expected, this apoenzyme does not contain any metals in the active site, but a glycerol molecule is bound as in the native enzyme. A water molecule is located at position M1; consequently, O3 of the glycerol has shifted 1.4 Å toward His272 (Figure 4B).

To determine if and how other metals bind to PirXI, crystal soaks were performed. Several structures of binary and ternary complexes of PirXI with metals, substrates, and inhibitors were determined (Table 1 and Table S1).

Mg, Xylose, and Xylitol Binding. In electron density maps of crystals of the apoenzyme soaked with magnesium and glycerol or with magnesium and the competitive inhibitor (or substrate analogue) xylitol,28 only a single Mg2+ ion at the M1 site was observed (Figure 5A,B). There was no 2Fo−Fc density present for the Mg2+ ion at position M2, despite the presence of Mg2+ in the soak solution at 10 mM (Figure S2). Glycerol was bound as in the native PirXI crystals. The position of xylitol was overlapping with that of the glycerol molecule in the Mg−glycerol structure, but the larger xylitol molecule bound deeper in the active site toward the putative M2 position. Xylitol was bound with its O1 atom bound to NE2 of His272 and a water molecule, O2 to Glu233, Glu269, Asp340, and M1 (Mg2+), O3 to Asp340 and a water molecule, O4 to Glu233 (bidentate), Asp297, Asp340, and M1, and O5 to NE2 of His102 and a water molecule (Figure 5B). His102 is likely involved in pyranose ring opening.26,57

Only when a soak was performed with magnesium and the substrate D-xylose was the second metal site (M2) fully occupied with elongated (elliptical) electron density, showing two distinct positions for the metal, with approximately 50/50 occupancy, at distances of 3.8 Å (M2b) and 5.5 Å (M2a) from M1 (Figure 5C). It has been elucidated by structural studies, including neutron diffraction, that the hydride shift of the isomerization reaction is mediated by the metal at M2.25,26,58,59 In the Mg−xylose structure, the substrate is in its open form in the same conformation as xylitol, indicating ring opening has been completed. At the current resolution of the data sets (1.9 Å), it is not possible to distinguish between the linear forms of the substrate and product by electron density, and probably a mixture of both is bound. The open chain forms are similar in shape, and differences exist at only C1 and C2, having sp3 or sp5.
The active site structure of PirXI, bound substrates are in a linear form (XLS) in subunit A and subunit B, while in subunit C and subunit D of the yin–yang dimer, the substrates are in the pyranose ring form (Figure 6A,B). This mixture of open and closed structures was observed for only the PirXI–Cd structure. For PirXI structures soaked with other metals, the electron density map showed only the linear form of the substrate in the active site (Figure 5B–D). The active site structure of PirXI–Cd with the xylose in a linear form is very similar to the structure of Mg–xylitol. Cd\(^{2+}\) at M2b is observed at two distinct positions with a 1.4 Å distance from that in class I XI from A. missouriensis complexed with Cd\(^{2+}\) and sorbitol (PDB entry 2XIN). The residues involved in the metal binding sites are shown as green sticks. His102 is colored salmon. The sorbitol molecule is colored yellow. The residues and sorbitol from 2XIN are colored gray. Mn\(^{2+}\) ions are shown as purple spheres and Co\(^{2+}\) ions as pink spheres. Interactions between the metal ions and hydroxyls of the sorbitol are shown as dashed lines.

**Figure 6.** Active sites of (A) Cd–linear XLS–XI and (B) Cd–cyclic XLS–XI. The residues involved in the metal binding sites are shown as green sticks. His102 is colored salmon. The xylose molecules are colored yellow. Cd\(^{2+}\) ions are depicted as light orange spheres, and interactions between the metal ions and the hydroxyl groups of xylose or the protein environment are shown as dashed lines. The difference electron density, $F_o - F_c$, contoured at the 2σ level for the sugars is shown.

**Figure 7.** Overlay of the active sites of Mn–SOR–XI and XI from A. missouriensis complexed with Co\(^{2+}\) and sorbitol (PDB entry 2XIN). The residues involved in the metal binding sites are shown as green sticks. His102 is colored salmon. The sorbitol molecule is colored yellow. The residues and sorbitol from 2XIN are colored gray. Mn\(^{2+}\) ions are shown as purple spheres and Co\(^{2+}\) ions as pink spheres. Interactions between the metal ions and hydroxyls of the sorbitol are shown as dashed lines.
XI—Ni, XI—Fe, and XI—Ca. The XI—Fe structure contains two iron atoms in the active site 1.9—2.2 Å from the surrounding ligands (Figure S3A). No glycerol molecules could be observed in the electron density, which could be caused by the lower resolution of the data set. The M2 Fe$^{2+}$ is positioned at the M2b location 2.4 Å from His272. The Fe$^{2+}$ atoms are positioned 3.8 Å from each other.

A soak with xylose of a Ni$^{2+}$-grown XI crystal reveals xylose in its linear form in the active site (Figure S3B). Its position superimposes well on the Mg$^{2+}$—xylose structure. The Ni$^{2+}$ cation at position M2 has two distinct locations (M2a and M2b), as in the Mg$^{2+}$—xylose structure. However, Asp308 does not have the double conformation as observed in the Mg$^{2+}$—xylose structure.

A soak with Ca$^{2+}$ resulted in both positions M1 and M2 being occupied (Figure 8A). M2 is bound in a distorted octahedral geometry by His272 at 3.4 Å, Glu269 at 2.3 Å, Asp308 at 2.2 Å, Asp310 at 2.4 Å, and two water molecules. To the best of our knowledge in Class I XIs, the M1 site was never occupied by a Ca$^{2+}$ ion. At M2, other class I XIs bound Ca$^{2+}$ at the M2a position, similar to what we observed in the PirXI—Ca$^{2+}$—xylose structure, but the equivalent residue of Asp308 binds the M2 in a bidentate manner in other enzymes. The large size of M2—Ca$^{2+}$ shifts Asp308 and Asp310 slightly out and the O1 position of the linear xylose by 1.5 Å toward Phe61'. This leaves the substrate in an unfavorable position for isomerization.

XI—Mn, XI—Co, and XI Substrate/Product. The PirXI structure with two manganese ions and the substrate xylose well represents the most active form of the enzyme (Figure 8A). The Mn$^{2+}$ at position M1 has its usual octahedral coordination, while M2 has full occupancy at the catalytic M2b position (no occupation of the M2a site). The M1 and M2b metal binding sites are 4.1 Å distance from each other. M2b is coordinated by His272 at 2.4 Å, Glu269 at 2.3 and 2.9 Å, Asp308 at 2.0 Å, Asp310 at 3.2 Å, and O1 of xylose at 2.8 Å and O2 at 2.7 Å. The coordination is highly similar to that observed in the A. missouriensis XI (9XIM) mutant E186Q ternary complex with two Mn$^{2+}$ atoms and a linear xylose. It is interesting that in the PirXI structure with the highest activity, which is the Mn$^{2+}$-dependent activity (Table 2), only the M1 and M2b sites are occupied, not M2a.

Xylose was soaked in a Co$^{2+}$ cocystalized crystal and cryoprotected with 2 M proline. The structure showed that M2—Co$^{2+}$ ion occupies two positions (M2a and M2b) with a 1.8 Å distance (Figure 8B). Furthermore, similar conformational changes for Asp308, Asp310, and Phe61' are observed as in the Mg$^{2+}$—xylose structure. In this structure, we modeled d-xylose as it was present at a concentration of ~0.25 M in the soaking solution. The position is similar to that of the xylose found in the crystal structure of St. rubiginosus (1XII) and in the neutron diffraction structure of St. rubiginosus (3XWH).

**DISCUSSION**

An efficient xylose isomerase that is well expressed in the active form in S. cerevisiae is critically important for the development of xylose-fermenting yeast strains. The Pironymes sp. E2 xylose isomerase has emerged as an attractive enzyme for this purpose. Our recent work indicates that metal incorporation is critical for in vivo activity, as suggested by the effect of mutations influencing manganese homeostasis on XI activity and anaerobic xylose metabolism. Our work corroborates this by exploring the metal dependence of the catalytic performance and by examining crystal structures of the enzyme soaked with different metals, substrates, and substrate analogues.

Studying the metal dependence of the catalytic activity, we observed that xylose isomerization of PirXI can be activated by various bivalent metals, but the level of activity is dependent on the metals. The enzyme was not activated by a trivalent metal such as Al$^{3+}$. Previous structural studies of XI from Arthrobacter showed that binding of the metal at M2 and substrate binding were disturbed when the enzyme was soaked with Al$^{3+}$ and xylose or fructose. Such a dependence of activity on the type of metal that is bound was also observed in previous studies.

It seems that the class I and class II xylose isomerases have different metal preferences as they mostly show the best activity with Mg$^{2+}$ and Mn$^{2+}$ metal cofactors, respectively. As a class II xylose isomerase, PirXI indeed also showed the highest activity with Mn$^{2+}$. Here, we explore the metal dependence of the enzyme by analyzing the structural differences in PirXI reconstituted with different ligands (metals/substrate or analogues) and interpreting the effects on the enzyme activity in view of the proposed catalytic mechanism of xylose isomerases.

The isomerase mechanism includes at least three chemical steps, accompanied and enabled by proton transfer reactions: ring opening of the substrate, hydride transfer from C2 to C1 accompanied by proton transfer from O2 to O1, and ring closure (Figure 1). Structural analysis of xylose isomerase from St. rubiginosus showed that the reaction involves movement of one of the metals (M2, the catalytic metal) and rotation of some of the active site residues such as Asp255 and Lys289,
which correspond to Asp308 and Lys342, respectively, in PirXI.26

The His102-Asp105 pair, which is conserved throughout xylose isomerase sequences, is involved in ring opening of the substrate that is bound to M1.26 This ring-opening step seems to be dependent on the metals that are bound to the enzyme. In the structure of PirXI with Cd2+ and xylose, the substrate is found in both cyclic and linear form (Figure 6A,B). This indicates a slow ring opening that led to the very low enzyme activity in the presence of Cd2+. For many xylose isomerases, Cd2+ is reported to inhibit the enzyme reaction, probably by preventing the ring opening of the substrates as the structure with this metal shows only the cyclic form of the substrate.26

After linearization of the substrate M2a that is coordinated with three aspartates, a histidine, and a water molecule shifts to M2b where it now coordinates O1 and O2 of the sugar and must therefore be in the catalytically competent position.26 The mobility of the M2 metal is supposed to aid the reaction after ring opening to facilitate isomerization in its linear form.26,31 A structure of the catalytically most competent enzyme (Mn2+ and xylose bound) revealed that Mn2+ occupies only the M2b position of the two conformations at the M2 site (Figure 8A). This might indicate that the rapid or more complete shift of the metal from M2a to M2b contributed to the higher activity of the enzyme in the presence of Mn2+ compared to other metals. The kcat of PirXI−Mg2+ is half that of PirXI−Mn2+, and in the enzyme structure with Mg2+, the metal is observed at positions M2a and M2b. In the structure of PirXI−Ca2+, the M2 metal is found at only the M2a position (Figure 8A). The large size of Ca2+ could hamper its movement, which may be one of the causes of the low rate of reaction of PirXI with this metal.

Variations in transition state stabilization of the actual hydride transfer steps among the different metals bound in the M2b site may also contribute to the observed differences in activity. Movement of the metal at position M2 does not necessarily mean that the metal can activate the enzyme. Although Ni2+ was found at both M2 positions, the enzyme showed no detectable activity (Figure S3B). The presence of Ni2+ at two distinctive M2 positions was also observed in the structure of St. rubiginosus XI, which is also inactive with the metal.26 After the ring opening of the substrate, Ni2+ may be incapable of inducing the polarization of the catalytic water necessary to proceed with isomerization. This inhibiting effect of Ni2+ has been explained by the preference for square planar coordination and its high electron affinity.26

PirXI is also active with Fe2+ as the metal cofactor, and the specific activity was ~70% of that of PirXI−Mg2+. PirXI−Fe2+ shows two iron ions in the active site (Figure S3A). Although the reaction of PirXI in the presence this metal was performed under O2-limited conditions, we cannot exclude the possibility of Fe2+ partially being oxidized to Fe3+, which would influence the activity. Strong inhibition of a class II XI by iron has been described26 and PirXI is one of a few xylose isomerases reported so far that shows activity on xylose with the Fe2+ cofactor.68,69

Binding of substrate is also dependent on the type of metal cofactor bound to PirXI. As the ionic radius of Ca2+ is larger (1.14 Å) than those of other metals, the carbonyl and the 2-hydroxyl of the bound xylose are shifted away from the M2 site, placing the substrate in a position that is not favorable for catalysis (Figure 8A). This could explain the extremely high KM for xylose in the presence of Ca2+, whereas it is relatively low with Mg2+ or Mn2+. PirXI−Co2+ shows the highest affinity for xylose, which led it to have the highest catalytic efficiency. However, this may be hardly relevant in vivo as cobalt is a less abundant metal and metal content analysis showed that almost no cobalt was bound to the purified native PirXI.

While the metal cofactors influence substrate binding, the type of substrate/inhibitor seems to influence the binding of the second metal. In the crystal structure of PirXI−Mg2+ with either xylitol or glycerol, only position M1 is occupied by a metal. This indicates that the binding of the metal at position M2, in the case of Mg2+, requires a proper binding of the substrate as observed in the PirXI−Mg2−xylose structure. The absence of metal binding at position M2 in the presence of an inhibitor such as xylitol and sorbitol has also been observed in structures of other XIs.55,61,62

As shown in the structure of PirXI with sorbitol, binding of a C6 sugar is different between PirXI and class I enzymes (Figure 7). Because of a bulky tryptophan at position 140, which is substituted with a Met in the class I enzymes, binding of the C6 sugar is sterically hindered in PirXI. In the structure of a class I XI from Arthrobacter strain B3728, it was shown that O6 of the α-sorbitol was pointing toward the methionine residue.70 Indeed, the activity assays of PirXI show that the enzyme is barely active with glucose (very low kcat and high KM), whereas the class I enzymes have higher activity with glucose.32 In a previous study of another class II XI from C. thermosulfurogenes, replacing the tryptophan with the smaller phenylalanine improved both KM and kcat of the enzyme for glucose, proving that the steric hindrance of the tryptophan was responsible for the poor activity of the enzyme toward C6 sugars. Nevertheless, this property of PirXI makes it more favorable as a specialized catalyst for lignocellulosic bioethanol production as the enzyme will be devoted to only converting xylose to xylulose.

As we have revealed the impact of various metals on the kinetic properties of PirXI, it is important to understand the in vivo metal binding of the enzyme and how it influences its activity. In this study, we have measured the metal content of PirXI isolated from E. coli. The enzyme was found to bind a mixture of several metals, and the contents were different depending on the cultures from which the enzyme was purified. This indicates that the metal contents of the overexpressed enzyme can be influenced by the intracelluar metal composition as well as the enzyme−metal affinity. Therefore, measurements of xylose isomerase activities with cell-free extracts or with enzyme samples of which the metal content is not strictly controlled by reconstitution of chelator-treated apoenzyme may give results that have little significance because of variations in metal content, some of which may be introduced during sample preparation. Thus, the medium composition, expression level, and growth phase of cultures may influence metal availability and apparent XI activity.67,69

Previously, Hlima and colleagues found that the recombinant xylose isomerase from Streptomyces sp. SK expressed in E. coli has activity lower than that of the native enzyme, which was explained by the lack of posttranslational modification.71 However, overexpression of the recombinant enzyme could have led to the different metal contents and, hence, the different activities. In a recent study, we have shown that intracellular metal contents play a critical role for the in vivo activity of PirXI expressed in S. cerevisiae as it influences metal loading of the enzyme and, thereby, the in vivo catalytic activity and the rate of xylose metabolism.53
Although the total metal contents of the purified enzyme were close to the theoretical value (two metal ions per monomer of PirXI), it seems that the enzyme loses some of the metals during sample preparation for crystallization. The crystal structure of native PirXI showed that only M1 was occupied, which indicates stronger metal binding at M1 than at M2. Interestingly, His272, one of the M2 metal-coordinating residues, was shown to be doubly protonated by the time, and this could cause weak binding of the metal,\(^26,58\) although this could be dependent on the type of metal. The refinement of the structure with different metals at M1 showed that the occupancy of metals decreases in the following order: Ca\(^{2+}\) > Mg\(^{2+}\) > Fe\(^{3+}\). Because the metal content analysis showed that the enzyme bound mainly Mg\(^{2+}\) and lower levels of Ca\(^{2+}\) and Fe\(^{3+}\), we speculate that more Mg\(^{2+}\) was bound at M2 than at M1 in native PirXI. Different affinities of various metal ions for the M1 and M2 binding sites were also observed in previous studies, and the metal preferences differ between the isomerases. For instance, XI from *Arthrobacter* B3728 showed a high affinity for Mn\(^{2+}\), Co\(^{2+}\), Cd\(^{2+}\), and Pb\(^{2+}\) at M2 and Mg\(^{2+}\) and Al\(^{3+}\) at M1, while XI from *St. rubiginosus* prefers Mg\(^{2+}\) at position M1 and other various metal ions at position M2.\(^26,61,70\)

In the study presented here, we measured the activation constants \(K_{act}\) of different metals, which are probably determined by the binding site with the lower affinity. PirXI has the highest affinity for Mn\(^{2+}\), which is also the superior metal for enzyme activity. The affinity of the enzyme for different metals does not necessarily correlate with the chemical reactivity of the metals for the isomerization reaction. Even though the \(K_{act}\) for Co\(^{2+}\) is much lower than that for Mg\(^{2+}\), the enzyme is more active with Mg\(^{2+}\). Interestingly, the metal binding affinity of XI from an *Arthrobacter* strain is similar to that of PirXI (Mn > Co > Mg), but this enzyme shows the highest activity in the presence of Mg\(^{2+}\).\(^30\) As metal binding residues in xylose isomerases are highly conserved, it is likely that the different chemical reactivity of a metal in different XIs is influenced by the overall protein environment, including second-shell residues and perhaps the residues that are farther from the active site.

The results reported here reveal clear differences between different metals with respect to the binding mode, affinity, and catalytic activity of PirXI. The various assays and crystallography experiments were performed with the apoenzyme reconstituted with different metals. Several factors, including metal-dependent PirXI activity, metal availability, and metal affinity, could affect the efficiency of the enzyme *in vivo*. It is possible that further exploration using mixtures of metals will be necessary to fully understand the *in vivo* activity of the enzyme. Previously, the activities of PirXI in the presence of metal mixtures that represented the *in vivo* metal composition of different *S. cerevisiae* strains showed that Mn\(^{2+}\) influenced the overall activity significantly, despite it being a minor component of the overall mixtures.\(^33\) This suggests a higher affinity of the enzyme for this metal, in agreement with the current half-saturation constants \(K_{act}\). On the other hand, an inhibitory effect of Ca\(^{2+}\) was not pronounced at concentrations mimicking the *in vivo* levels, as the activities with the metal mixtures were as high as the activity with Mg\(^{2+}\) alone.

Besides metal content, the pH dependence of XI may be important for the *in vivo* activity. PirXI shows an optimum pH of \(\geq 7.5\) in the presence of Mg\(^{2+}\), Mn\(^{2+}\), and Ca\(^{2+}\). The enzyme activity decreases rapidly at pH <6.5, and this decrease is thought to be related to the local pKa of His272, which is involved in metal (M2) coordination, or Lys342, which in turn interacts with the metal binding residue Asp310.\(^26\) The pH–activity profile seems also to be dependent on the metals as PirXI–Co\(^{2+}\) showed a pH profile different from that of the enzyme with other metals. The activity of PirXI–Co\(^{2+}\) is unaffected by the pH, at least in the range of 5.5–7.5. The pH profiles of xylose isomerases of different biological origin may vary. Some show the best activity in the acidic pH range,\(^71–74\) and some are most active in the neutral pH range \(3,69,75\) or the basic pH range.\(^32,76\) Comparing the sequences and structures of these XIs with different pH optima will be useful for engineering PirXI to optimize its activity for the cytosolic pH of the *S. cerevisiae*.

**CONCLUSIONS**

Xylose isomerase from *Piromyces* sp. E2, which catalyzes xylose isomerization in metabolically engineered *S. cerevisiae* strains for conversion of pentoses to ethanol, can accept various metals. The catalytic performance of the enzyme is dependent on the type of metal that is bound, with Mn\(^{2+}\) being the best metal, followed by Mg\(^{2+}\), Ca\(^{2+}\) and Cd\(^{2+}\) poorly activate the reactions, and Ni\(^{2+}\) and Al\(^{3+}\) are not activating. Because there is no clear correlation between the metal-dependent activities and the affinity of the enzyme for metal ions, *in vivo* XI performance will be influenced by the availability of metal in the medium, uptake and distribution of metal in cells, and incorporation of metal into the enzyme.

Overall, the PirXI crystal structures are similar to other XI structures, the major differences being the N-terminal \(\alpha\)-helix extension and the size of the interface area in the tetramers as compared to class I XIs. The active site of each PirXI subunit contains a substrate binding site and two metal binding sites formed by several aspartates and glutamates that are conserved throughout XIs. The results of soaking experiments confirmed that PirXI is highly promiscuous with respect to metal binding and suggest that differences in movement of the catalytic metal to a position required for hydride-shift catalysis and associated conformational changes of metal binding side chains may be related to differences in catalytic performance.

Understanding the metal-dependent catalytic properties of the enzyme through structural and biochemical studies as described in this study provides critical insights for enzyme engineering to optimize the *in vivo* enzyme activity, thereby improving the production of ethanol from xylose.

REFERENCES
Bacterial xylose isomerase (xylose isomerase) has been extensively studied due to its ability to catalyze the interconversion of D- and L-xylose, which are important monosaccharides that are prevalent in lignocellulosic biomass. This enzyme plays a crucial role in the utilization of xylose by microorganisms, and its properties have been extensively investigated. The paper highlights the importance of understanding the three-dimensional structure of xylose isomerase in order to clarify its biocatalytic properties. Furthermore, the study emphasizes the role of xylose isomerase in the catalysis of aldose-ketose interconversion, which is a fundamental process in carbohydrate metabolism.

The paper discusses the recent advancements in the structural biology of xylose isomerase, with a focus on the crystallographic studies. The authors provide a comprehensive overview of the structural features of xylose isomerase, including its active site and the role of critical residues that contribute to its catalytic activity. The paper also highlights the importance of understanding the binding modes of substrates and inhibitors to xylose isomerase, which is essential for the development of xylose isomerase-based biocatalysts for industrial applications.
