INTRODUCTION

Organic/inorganic hybrid perovskite materials, such as CH$_3$NH$_3$PbI$_3$, have attracted tremendous attention as promising candidates for diverse optoelectronic applications because of their unique optical and excitonic properties, as well as their long carrier diffusion length. Moreover, these hybrids exhibit a wide range of tunable band gaps and are easy to synthesize. In addition to solar light conversion, other optoelectronic applications of this class of materials have recently been reported owing to their outstanding properties. These applications include light-emitting diodes, field-effect transistors, nonvolatile memories, lasers, and photodetectors. Recently, many advances have been made to improve the quality of thin films and study the effect of moisture on the film formation. However, the application of these luminescent materials in display screens and similar devices requires patterning. This patterning should be composed of dense and uniform crystalline structures, without harming the optical properties of the materials.

The most commonly used micropatterning method in materials is photolithography, which requires complex and expensive photolithographic and etching equipment. Furthermore, a new etching procedure must be developed each time a new material is introduced. Therefore, soft lithography techniques have gained more interest as low-cost methods for creating micrometer- and submicrometer-sized structures, in particular those that are additive techniques. These methods require a hard or an elastomeric stamp that is patterned with a relief structure on its surface. The structures can be transferred to the material by various methods, which include imprint lithography and micromolding in capillaries (MIMIC). Imprint lithography is a method in which a prepatterned stamp is gently pressed into a liquid precursor film on a substrate. The MIMIC technology involves bringing a prepatterned stamp and a substrate into conformal contact to form micrometer-sized capillaries between the stamp and the substrate. After placing the precursor solution at one end of the stamp, the channels are spontaneously filled by capillary forces. However, the application of these luminescent materials in display screens and similar devices requires patterning. This patterning should be composed of dense and uniform crystalline structures, without harming the optical properties of the materials.

Recently, a few studies reported methods to fabricate micropatterns of the three-dimensional (3D) organic/inorganic hybrid perovskite CH$_3$NH$_3$PbX$_3$ (X = I, Br), but only a limited amount of work has been reported on the patterning of...
two-dimensional (2D) hybrids. In most cases, 2D hybrids allow for handling under ambient conditions as they exhibit enhanced moisture stability compared to their 3D counterparts. Generally, 2D hybrid structures consist of single (100)-terminated perovskite sheets separated by bilayers of organic cations, which are held together through van der Waals interactions. Because of their quantum well structure and enhanced dielectric confinement, stable excitons with large binding energies can be formed within these materials. Such high exciton binding energies are generally disadvantageous for solar cell applications, but these 2D structures can exhibit enhanced conduction within the layers and have potential applications in other optoelectronic devices, such as light-emitting diodes. Furthermore, 2D organic/inorganic hybrid materials allow for a large set of organic cations to be incorporated into the crystal structure and therefore for a broad range of tunable band gaps for desired applications.

In this work, we focus on 2D benzylammonium lead iodide, (C\textsubscript{6}H\textsubscript{5}CH\textsubscript{2}NH\textsubscript{3})\textsubscript{2}PbI\textsubscript{4}, which forms orange crystals with a direct band gap in the range of 2.12–2.19 eV. We investigate and compare both imprint lithography and MIMIC technology, with which we obtain line patterns of (C\textsubscript{6}H\textsubscript{5}CH\textsubscript{2}NH\textsubscript{3})\textsubscript{2}PbI\textsubscript{4} with micrometer-scale resolution. Although we demonstrate the successful formation of uniform arrays of (C\textsubscript{6}H\textsubscript{5}CH\textsubscript{2}NH\textsubscript{3})\textsubscript{2}PbI\textsubscript{4} using both methods, the choice of method is found to have an influence on the long-range quality of the patterns. Surprisingly, X-ray diffraction (XRD) reveals that micropatterning induces a strong preferential orientation of the crystallites, as compared to nonpatterned, drop-casted films. Furthermore, photoluminescence (PL) measurements reveal that the optical properties of (C\textsubscript{6}H\textsubscript{5}CH\textsubscript{2}NH\textsubscript{3})\textsubscript{2}PbI\textsubscript{4} are maintained during patterning. Notably, our results show that the micropatterns contain larger grain sizes than the nonpatterned films and therefore give rise to an enhanced PL lifetime. Thus, our results demonstrate easy and cost-effective ways to manufacture patterns of 2D organic/inorganic hybrid perovskites, while maintaining their optical properties and even improving the PL lifetime. This potentially allows for the use of color-tunable 2D hybrids in optoelectronic devices.

### EXPERIMENTAL SECTION

#### Materials Synthesis.

The organic precursor salt was synthesized by slow evaporation of an equimolar mixture of HI (Sigma-Aldrich; 57 wt % in H\textsubscript{2}O) and benzylamine (Sigma-Aldrich; 99%). After slowly adding HI to benzylamine, stirring to mix both components and heating on a hot plate at 60 °C, a white salt was formed. Once the solvent was fully evaporated, the crystallized salt was washed three times with diethyl ether (Avantor) and dried in a vacuum oven at 120 °C overnight. PbI\textsubscript{2} (Sigma-Aldrich; 99%) was used as the inorganic precursor. The organic/inorganic precursor solution was prepared by dissolving the organic and inorganic salts in an equimolar ratio in dimethylformamide (DMF, Sigma-Aldrich), yielding a concentration of 0.1 M.

#### Preparation of PDMS Stamps.

A variety of 0.5 × 0.5 cm\textsuperscript{2} polydimethylsiloxane (PDMS) stamps (around 6 mm thick) were fabricated by curing the silicone elastomer and its curing agent (Sylgard 184, Dow Corning) in a 10:1 weight ratio on a prepatterned Si master and cutting 0.5 cm\textsuperscript{2} fully patterned sections out of the master. Note that the cured PDMS stamps always contain some nonreacted low-molecular-weight monomers, which will slowly migrate to the surface of the stamp and leave traces on the substrate during microcontact printing or other patterning techniques. To silanize the master, we used a vacuum process inspired by the work of Xia and Whitesides. Here, 10 μL of trichloro(1H,1H,2H,2H-perfluorooctyl)silane (Sigma-Aldrich, 97%) was added to a desiccator containing the Si master in an argon-filled glovebox. Once brought under vacuum, silanization took place overnight, and the Si master was stored thereafter. The elastomer was degassed to remove all air bubbles, cured at 40 °C overnight, and then peeled gently off the master. Note that the cured PDMS stamps always contain some nonreacted low-molecular-weight monomers, which will slowly migrate to the surface of the stamp and leave traces on the substrate during microcontact printing or other patterning techniques. To extract the low-molecular-weight fraction, we soaked the PDMS stamps in EtOH for 6 days, before drying them on a hot plate at 50 °C for 1 h and storing in a closed box.

#### Patterning of the Films.

The patterning of the films was performed on glass substrates by two different patterning techniques: imprint lithography and MIMIC technology. First, the glass substrates (around 2 × 2 cm\textsuperscript{2}) were cleaned with 2-propanol and then with oxygen plasma for 15 min to make the surface polar. For the imprint technique, 50 μL of the precursor solution (with a viscosity of 0.92 mPa s) was drop-casted onto the clean glass substrate, prior to slowly pressing the PDMS stamp into the precursor solution (i.e., imprinting). A home-built micromolding machine was used for perfect parallel alignment of the stamp with the substrate by applying a
The stamps and substrates were cured under pressure for 2 h at 80 °C. After carefully removing the stamps and the excess precursor, the patterned substrates were stored. For the MIMIC method, the PDMS stamp was placed in conformal contact with the clean substrates, with an applied pressure of ∼0.5 bar. As a result, the channels of the stamp formed capillaries with the substrate. Thereafter, the precursor solution was deposited at one end of the channel-shaped stamps, and the channels were spontaneously filled by capillary forces. The stamps and substrates were cured under applied pressure for 2 h at 80 °C. After carefully removing the stamps and the excess precursor, the patterned substrates were stored.

**RESULTS AND DISCUSSION**

We patterned microstructures of the organic/inorganic hybrid perovskites [(C₆H₅CH₂NH₃)₂PbI₄] on glass substrates using both micropatterning techniques, as illustrated in Figure 1. The glass substrates were plasma-cleaned in all cases to make them polar. For comparison, we also prepared nonpatterned thin films by drop-casting a small amount of the precursor solution (50 μL) onto a glass substrate (see Figure 1c). The precursor solution immediately spread into a uniform thin layer (of the order of 1 mm), and a polycrystalline film was obtained after thermal annealing.

As shown in Figure 1, the two micropatterning procedures differ from each other in the order in which the prepatterned PDMS stamp and the precursor solution are introduced. For the MIMIC technology, the stamp and the polar substrate are brought into conformal contact, forming capillaries between the stamp and the substrate. Once the precursor solution is introduced at one side of the stamp, the channels are spontaneously filled by capillary forces. The general advantage of this technique is that the stamp is brought into conformal contact with the substrate before introducing the precursor solution. Therefore, residual layers of the precursor between the patterned structures are avoided. A limiting factor for making well-defined patterns is the viscosity of the precursor solution, which should be low enough to allow a viscous flow. Moreover, a disadvantage of the MIMIC technology is that patterning isolated features is impossible. Imprint lithography describes the method in which a prepatterned stamp is gently pressed onto a liquid precursor film on a substrate. Imprint lithography has the advantage over MIMIC technology that it is also applicable to solvents that do not spontaneously wet the substrate and the PDMS mold. Furthermore, isolated features can also be patterned. The main disadvantage is the possible formation of residues between the patterned structures, resulting in lower-quality structures. Both patterning methods can also be applied to monomeric precursors and polymer melts, but the choice of our organic/inorganic hybrid precursor requires that both methods employ precursor solutions.

**Figure 2.** Optical microscopy images of micropatterned (a,b) and drop-casted thin films (c) of (C₆H₅CH₂NH₃)₂PbI₄. The micropatterned films were obtained by MIMIC technology (a) and imprint lithography (b). The feature size is smaller than 5 μm.

**Figure 3.** Top-view (a,b) and cross-sectional (c,d) SEM images of micropatterned thin films of (C₆H₅CH₂NH₃)₂PbI₄. The micropatterned films were obtained by MIMIC technology (a,c) and imprint lithography (b,d).
solvent.\textsuperscript{34,35} Figure S1 in the Supporting Information shows SEM images at lower magnification, covering a larger area. Here, the imprinted pattern appears very uniform over longer distances, whereas the pattern made using MIMIC technology appears to have more defects. The general quality of the MIMIC patterns is high, but this method is very sensitive to local disturbances. A single defect or obstruction in a channel will prevent the rest of the channels from becoming filled and therefore yield an incomplete pattern. Defects will only have a local influence with imprint lithography, as the precursor solution is already present everywhere in the channel before curing. Thus, MIMIC technology is based on a more dynamic process than imprint lithography and requires more parameters to be optimized to form a uniform pattern. Therefore, we reason that imprint lithography would be a more suitable method for larger-area printing than MIMIC technology. From a practical and engineering point of view, imprint lithography is hence the preferred method.

Comparison of the cross-sectional SEM images in Figure 3c,d shows different height profiles for the two patterning methods. Neither method yielded structures with a height corresponding to the channel height of the master (8 \( \mu \)m). The reason for this is that the channels are fully filled with the diluted liquid precursor solution, but upon drying, only a relatively small volume of the crystalline material remains. However, a simple calculation, taking into account the crystal density, the channel size, and the molarity of the precursor solution, shows that the expected pattern height in a dried channel would only be 0.27 \( \mu \)m. Notably, Figure 3c,d shows feature heights of 6.80 and 7.25 \( \mu \)m for MIMIC technology and imprint lithography, respectively. However, these are typical average feature heights, and there are some variations across different lines in each sample. The patterns made by the MIMIC method have feature heights in the range of 6 to almost 7 \( \mu \)m (no features were \>7 \( \mu \)m in height), whereas the patterns made by imprint lithography have feature heights in the range of 6 to almost 7.5 \( \mu \)m, with several examples of features \>7 \( \mu \)m in height. No variation in height was observed along the channel length. Note that it is not possible to use atomic force microscopy (AFM) techniques to scan the surface, as the structural features are too large.

The formation of these high structures implies that around \( 25\times \) (for the 6.80 \( \mu \)m feature made with MIMIC technology) and \( 27\times \) (for the 7.25 \( \mu \)m feature made with imprint lithography) more solid material accumulated in the channels than expected. Previous work on micropatterns of yttrium-stabilized zirconia, using MIMIC technology, showed that around 7.5\( \times \) more solid material accumulated in the channels than that was present in the equivalent volume of the liquid precursor solution.\textsuperscript{36} It was hypothesized that this accumulation was explained by the high permeability of the precursor solvent into the micropores of the wall of the PDMS stamp, which enabled the new precursor solution from outside the stamp to be continuously dragged into the microchannels. We reason that the same mechanism can explain the high features in both types of line patterns here. Notably, the micropatterns obtained with both techniques yielded very high aspect ratios in the range of 1.5–1.8, while well-defined objects with aspect ratios above 1 are rarely reported.\textsuperscript{30}

We conclude that both patterning methods are suitable for generating organic/inorganic hybrid perovskite patterns, resulting in well-defined structures with very high aspect ratios. We found that imprint lithography yielded slightly higher structures and better large-scale structural uniformity. Moreover, as discussed in the Introduction, imprint lithography allows for isolated features to be patterned, whereas MIMIC technology does not. For example, microdots are typical features that are required for various applications. Another example of isolated features, that is, smiley faces, patterned by imprint lithography, is shown in Figure S2 in the Supporting Information.

Figure 4 shows the XRD profiles obtained for the micropatterned and nonpatterned films. All profiles were fitted using the 100 K atomic positions obtained from our previously reported single-crystal XRD data.\textsuperscript{37} The fits incorporated the March–Dollase preferred orientation model for crystallites aligned along the c-axis as implemented in the GSAS software.\textsuperscript{38} The XRD profiles confirm that both the patterned and nonpatterned films grew as a pure (C\(_6\)H\(_5\)CH\(_2\)NH\(_3\))\(_2\)PbI\(_4\) phase. However, both the imprinted and MIMIC patterns show a strong c-axis preferential orientation: only the 00\(l\) (\(l = 2n\)) peaks are present in the profiles. Spin-coating, a commonly employed method to deposit thin films of organic/inorganic hybrid perovskites, also generally yields highly c-axis-oriented films.\textsuperscript{39} In contrast, our nonpatterned drop-casted film exhibits a lesser degree of preferential crystallite orientation, as can be seen in Figure 4. The XRD pattern of the drop-casted film shows that the film is still highly c-axis-oriented, as evidenced by the strong 00\(l\) (\(l = 2n\)) peaks. However, the extra peaks observed in the pattern (indexed as 200, 020, and 400) indicate that the preferred orientation is not as strong as for the micropatterned films. Spin-coating generally leads to thinner films (tens or hundreds of nanometers) than our drop-casted film. We think that spin-coated films become crystallographically oriented because the spinning gives rise to fast evaporation and concentration saturation. The spin-coating process is very fast, as the meniscus of the precursor solution is formed by nucleation at the energetically most favorable location, that is, at the glass substrate interface. As a result, only heterogeneous nucleation occurs, and a highly c-axis-oriented film is formed. In contrast, drop-casting is a much slower method.
technique as the precursor solution is not forced to spread as rapidly as during spin-coating. As a result, there is time for both heterogeneous and homogeneous nucleation, and the presence of homogeneous nuclei disrupts the formation of a fully oriented film, as shown in Figure 4c.

To understand the mechanism by which micropatterning yields fully c-axis-oriented films, we have considered various influencing factors. First, the surface/volume ratio of the confined channel does not play any role. We confirmed this by patterning lines using a PDMS stamp with 80 μm wide channels (see Figure S3 in the Supporting Information). At such low aspect ratios, the precursor solution was mainly confined by the PDMS top surface rather than by the sidewalls. Still, a fully c-axis-oriented pattern was obtained. Because the orientation is not dependent on the influence of the PDMS sidewalls and ceiling, it can be concluded that nucleation most likely occurs at the polar glass substrate only. Second, we hypothesize that the preferential orientation in the micro-patterned structures is not caused by the drying rate. Although spin-coated films dry considerably faster than drop-casted films, we found that the micropatterns dried even more slowly than the drop-casted films while still yielding fully c-axis-oriented structures. The difference between the patterning and non-patterning processes is the limited mass transport rate in the channels because of the quasi-one-dimensional (1D) confinement, and the local accumulation of mass beyond the critical nucleation concentration is therefore less likely than in a quasi-2D film. The reason is that effective diffusion rates decrease when the dimensionality is reduced.46 The smaller mass fluxes in 1D geometries lead to smaller concentration fluctuations on the local scale, thereby lowering the chance of a nucleation event from occurring. Therefore, we infer that homogeneous nucleation is suppressed in the channels by both the physical confinement of the channel and the nonpolar nature of the PDMS stamp. As a result, highly c-axis-oriented patterns are formed following nucleation at the polar bottom interface. Thus, patterning not only gives rise to predefined microstructures by molding but also has a significant influence on the final orientation of the crystallites in the microstructure. We conclude that fully c-axis-oriented 2D organic/inorganic hybrids can be obtained by micropatterning, as an alternative to spin-coating techniques.

As stated in the Introduction, it is important that micropatterning gives rise to high-quality structures while maintaining the optical properties of the material. In Figure 5a, we show PL data from the micropatterns made using MIMIC technology and imprint lithography and from a nonpatterned, drop-casted film. The nonpatterned and patterned films yielded PL peaks at 543, 542, and 546 nm (2.28, 2.29, and 2.27 eV), respectively, which are slightly blue-shifted with respect to what we previously observed for single crystals of (C₆H₄CH₂NH₃)₂PbI₄ (2.12−2.19 eV).11 Note that films and crystals are not directly comparable, as their defects and trap densities can be different, resulting in the observations of slightly different band gaps.6 Additionally, work on related hybrid perovskites has shown great differences in quantum yield between nanocrystals and thin films.49 However, all three films in this work were polycrystalline and had comparable band gaps. Figure 5a shows that the PL peak of the patterned film made by imprint lithography is slightly broader than those of the nonpatterned film and the patterned film made by MIMIC technology. Moreover, a shoulder is apparent at longer wavelengths. As the patterned films made by MIMIC technology generally have fewer problems with the residues between the patterned features than the patterned films made by imprint lithography, we attribute this difference in the optical properties to the presence of more defects and vacancies in the imprinted film. The presence of defects and vacancies drives recombination in these systems and can result in interstitial bands that give rise to transitions at lower energy. Moreover, strong electron-vibration coupling effects in the deformable lattice and correlated self-trapped states play a role. In fact, broadband, white-light PL has recently been shown in a series of related 2D perovskite single crystals.50−52 Note that the patterned films made by MIMIC technology are of high quality, but that the large-area application of MIMIC technology is limited, as discussed above.

Figure 5b shows the corresponding TRPL spectra. Notably, the micropatterned films appear to have longer lifetimes than the nonpatterned film. From the graph, it is very clear that the MIMIC and the imprint spectra are nearly identical, but they clearly differ from the nonpatterned film. We found that the decay curves cannot be fitted with a monoexponential curve, as the decay appears more complex. The best way to deal with the multieponential decay in our material, without overparameterizing, is by fitting with a stretched exponential (Kohlrausch) function.54,55 The stretched exponential function $F(t)$ is given by

$$F(t) = F_0 \exp \left[ -\left( \frac{t}{\tau_0} \right)^\beta \right]$$

where $\tau_0$ is the effective time constant and $\beta$ (a constant between 0 and 1) is the stretch parameter that is a direct measure for the local heterogeneity of the sample, which is

Figure 5. (a) PL and (b) TRPL spectra measured on drop-casted and micropatterned thin films, using MIMIC technology and imprint lithography, respectively, of $(\text{C}_6\text{H}_4\text{CH}_2\text{NH}_3)_2\text{PbI}_4$. The decay curves of the drop-casted and micropatterned films (made by MIMIC technology and imprint lithography) are fitted with the stretched exponential function.
related to the width of the lifetime distribution. However, following the work of Zatryb et al.\textsuperscript{55} on PL decay, in our experiment, we did not measure the relaxation function directly. Instead, we measured the number of photons that are emitted in a very short time period after the excitation pulse. This number of photons is directly proportional to the change of the population of the excited emitters. Therefore, the decay of the PL intensity is given by a negative time derivative of the relaxation function, and hence, the stretched exponential function for PL decay becomes

\[ I_{\text{PL}}(t) = C \cdot t^{\beta - 1} \exp \left( -\frac{t}{\tau_0} \right)^\beta \]

where \( C \) is a constant. Figure 5b shows the fits using the following fitting parameters: \( \tau_0 = 79 \) ps and \( \beta = 0.57 \) for the drop-casted thin film and \( \tau_0 = 113 \) ps and \( \beta = 0.69 \) and \( \tau_0 = 115 \) ps and \( \beta = 0.68 \) for the micropatterned films, made by MIMIC technology and imprint lithography, respectively. The average decay time constant \( \tau \) can be determined by

\[ \tau = \frac{\tau_0}{\Gamma} \left( \frac{1}{\beta} \right) \]

where \( \Gamma \) is the gamma function. The average decay time constants are 127 ps for the nonpatterned film and 149 and 145 ps for the micropatterned films, made by MIMIC technology and imprint lithography, respectively. Thus, the PL lifetimes of the micropatterned films are nearly identical and enhanced with respect to the nonpatterned film.

Figure 6a shows the 008 XRD peak (K\( \alpha_2 \)/K\( \alpha_1 \) doublet) of the three samples. The peak width of the micropatterned films is significantly smaller than that of the nonpatterned film. This implies that the patterned films have larger crystallites than the nonpatterned films. As shown in Figure 6b–d, the nonpatterned films indeed have significantly smaller crystallites than the patterned films (bar-shaped crystallites). We believe that these small crystallites are formed by homogeneous nucleation and that they are responsible for the less oriented nature of these films. The small features also explain the longer lifetime of the patterned films, as larger crystallites exhibit a smaller radiative recombination coefficient, resulting in longer PL lifetimes.\textsuperscript{56,57} Because the slow drying process facilitates both homogeneous and heterogeneous nucleation events, a high concentration of nucleation points and hence small crystallites are obtained in the nonpatterned film. In the patterned structures, however, mass transport can occur in a 1D fashion because of the geometry of the channels. The MIMIC and imprint processes differ dynamically. At the moment the stamp is brought into contact with the precursor, the dynamical processes for MIMIC and imprint are not the same. However, crystallization occurs sometime after penetration has taken place or the stamp is brought into conformal contact with the substrate. At that moment, MIMIC and imprint are comparable as they both represent a stagnant situation in which no pressure-driven flow occurs and only 1D diffusional transport along the channel can occur while crystallization takes place. In this situation, fewer conflicting nucleation centers form and the material can be transported over longer distances, feeding nuclei and allowing the growth of larger grains. We conclude that micropatterning not only maintains the optical properties of (\( \text{C}_6\text{H}_5\text{CH}_2\text{NH}_3 \))\( \text{PbI}_4 \) but also enhances slightly the PL lifetime compared to nonpatterned, drop-casted films. The fact that the lifetime enhancement is the largest when MIMIC technology is used demonstrates an advantage of MIMIC technology over imprint lithography. However, the variation of the lifetime is rather small.

### CONCLUSIONS

We have investigated two different soft lithography methods to obtain line patterns of (\( \text{C}_6\text{H}_5\text{CH}_2\text{NH}_3 \))\( \text{PbI}_4 \) with high resolution: imprint lithography and MIMIC technology. Our results show the successful formation of uniform arrays of high-aspect-ratio (well above 1.5) (\( \text{C}_6\text{H}_5\text{CH}_2\text{NH}_3 \))\( \text{PbI}_4 \) micro-patterns using both methods. Although we find both methods to be applicable for the micropatterning of our organic/inorganic hybrid, the choice of method does have an influence on the characteristics of the patterns formed. Imprint lithography yields patterns with slightly higher features and better large-scale uniformity. Moreover, isolated features can be made with imprint lithography. MIMIC technology is based on a more dynamic process than imprint lithography and requires more parameters to be optimized to form a uniform pattern.

Because the XRD data demonstrate that micropatterning induces a strong preferential orientation of the crystallites compared to nonpatterned, drop-casted films, we conclude that fully c-axis-oriented 2D organic/inorganic hybrids can be obtained by micropatterning, as an alternative to spin-coating techniques. Furthermore, our (TR)PL measurements reveal that the optical properties of (\( \text{C}_6\text{H}_5\text{CH}_2\text{NH}_3 \))\( \text{PbI}_4 \) are maintained during patterning. Notably, the larger grain size obtained by patterning gives rise to an enhanced PL lifetime compared to nonpatterned drop-casted films. Thus, we have explored easy and cost-effective ways to manufacture patterns of 2D organic/inorganic hybrid perovskites, while maintaining and even enhancing their optical properties, and we find that the patterning technique used has an influence on the microstructure and therefore the optical properties of the films. This allows for the implementation of color-tunable 2D hybrid novel optoelectronic devices.
