Abstract

The aetiology of depressive disorder remains unknown, although genetic susceptibility and exposure to neurotoxins are currently being discussed as possible contributors to this disorder. In normal circumstances, the brain is protected against bloodborne toxic influences by the blood–brain barrier, which includes the molecular efflux pump P-glycoprotein (P-gp) in the vessel wall of brain capillaries. We hypothesized that P-gp function in the blood–brain barrier is changed in patients with major depression. Positron emission tomography was used to measure brain uptake of $[^{11}\text{C}]$verapamil, which is normally expelled from the brain by P-gp. Cerebral volume of distribution ($V_T$) of $[^{11}\text{C}]$verapamil was used as a measure of P-gp function. Both region-of-interest (ROI) analysis and voxel analysis using statistical parametric mapping (SPM2) were performed to assess regional brain P-gp function. We found that patients with a major depressive episode, using antidepressants, compared to healthy controls showed a significant decrease of $[^{11}\text{C}]$verapamil uptake in different areas throughout the brain, in particular in frontal and temporal regions. The decreased $[^{11}\text{C}]$verapamil uptake correlates with an increased function of the P-gp protein and may be related to chronic use of psychotropic drugs. Our results may explain why treatment-resistant depression can develop.

Introduction

A large body of evidence gathered during the past decades indicates that brain monoaminergic systems play a key role in the pathogenesis of affective disorders. However, not all symptoms of depression can be related to dysfunctions in monoaminergic systems. For instance, it is now known that stressful events paving the way to affective disorders, lead to changes in neuroplastcity, impair neurogenesis and may lead to a neuroinflammatory response in the brain (Trentani et al. 2003). As such, it has been suggested that a dysfunction of the blood–brain barrier (BBB) and blood–cerebrospinal fluid (CSF) barrier may contribute to the pathophysiology of major depressive disorder (MDD). Hampel and colleagues reported that serum/CSF ratios of several inflammatory proteins (used as an indirect measure of BBB function) were altered in depression (Hampel et al. 1995, 1997). Several endogenous substances, such as cortisol, are found in the brain parenchyma in high concentrations in subjects with a MDD. In normal circumstances the BBB limits the access of cortisol to the brain (Karssen et al. 2001).

The BBB is formed by the brain capillary non-fenestrated polarized endothelial cells that have high-resistance tight junctions. Besides low passive
permeability, the brain is protected from potentially harmful endogenous and exogenous substances by efflux transporter proteins, located in the brain capillary wall.

P-glycoprotein (P-gp), a product of the MDR1 gene in humans and the MDR-1a and MDR-1b genes in mice, is a major drug efflux transporter, involved in the efflux of a wide variety of lipophilic drugs and endogenous substances (Schinkel et al. 1994). Attenuation of P-gp function, for example through use of pharmacological inhibitors, results in substantial attenuation of P-gp function, for example through use of endogenous substances (Schinkel et al. 1994). The protective role of P-gp may be negatively influenced in neurodegenerative diseases. Animal models of neuroinflammation have demonstrated that P-gp is down-regulated by pro-inflammatory cytokines (Bauer et al. 2005; Fernandez et al. 2004; McRae et al. 2003).

In a recent PET study using [11C]verapamil it was found that the function of BBB P-gp was diminished in later stages of Parkinson’s disease, whereas de-novo patients with Parkinson’s showed a regional up-regulation of P-gp in frontal regions (Bartels et al. 2008a). In another [11C]verapamil PET study in patients with schizophrenia it was shown that P-gp function was locally increased (O. L. de Klerk et al. unpublished observations). The authors stated that P-gp induction may be critically involved in the development of drug resistance in schizophrenia. P-gp function is possibly under the influence of genetic polymorphisms (Hoffmeyer et al. 2000).

To date, no detailed evidence is available showing dysfunction of the BBB through P-glycoprotein modulation in MDD. It is not known whether P-gp function or expression is altered during a depressive episode.

In this exploratory study we hypothesized that P-gp function would be altered in limbic areas (hippocampus, amygdala) as well in frontotemporal areas (including anterior cingulate cortex) since these areas are known to play a role in depression (Drevets, 1999; Mayberg, 2002). We further hypothesized that this altered functional activity of P-gp could be connected to a genetic polymorphism of the MDR1 gene. To assess these hypothesized changes in P-gp function, PET brain imaging with [11C]verapamil as radiotracer was performed in depressed patients and healthy controls. The distribution volume of [11C]verapamil was used as a measure of total P-gp function.

**Methods**

**Subjects**

Fourteen patients suffering from depression were recruited and participated in the study. All underwent a Mini International Neuropsychiatric Interview (M.I.N.I. plus 5.0.0., Dutch version, 2000) for DSM-IV and fulfilled the criteria for a major depressive episode (Sheehan et al. 1998). Inclusion criteria for subjects with a major depressive episode were (1) age 40–80 yr; (2) fulfiment of DSM-IV criteria for major depressive episode; and (3) capacity to give informed consent. The age range 40–80 yr was chosen, because we expected to find larger differences at a later age in particular, since P-gp function declines with ageing (Bartels et al. 2008b). Moreover, the control group was also used in another study. Exclusion criteria were (1) use of known P-gp modulating agents (cardiovascular drugs, antimarial drugs, cyclosporine A, phenothiazines, hormones (e.g. tamoxifen), certain antibiotics such as cefoperazone, ceftriaxone, erythromycin) (Matheny et al. 2001); (2) any somatic disease of kidney, liver, heart or brain; (3) history of traumatic brain damage; (4) electroconvulsive treatment in the past 3 months; (5) abnormalities at clinical (including neurological) and laboratory examination; (6) pregnancy. Antidepressant medication was allowed. This research was approved by the Ethics Committee of the University Medical Centre Groningen, and all subjects gave written informed consent according to the Declaration of Helsinki. All patients had a minimum score of at least 19 on the 17-item Hamilton Depression Rating Scale (HAMD) at the time of the PET study (Hamilton, 1960). All patients had a physical examination and laboratory evaluation. All were in good physical health and none had meaningful laboratory abnormalities.

The healthy controls as well as their first-degree relatives were required to have no history of any psychiatric disease. The other inclusion and exclusion criteria for healthy controls were similar to the
patients. Before the scan, blood was drawn from the venous cannula for genotyping. Three common MDR1 single nucleotide polymorphisms (SNPs) were detected using a PCR analysis.

Radiochemistry

Racemic $[^{11}C]$verapamil was produced as previously described (Wegman et al. 2002). The injected radioactivity of $[^{11}C]$verapamil was comparable for the control group and subjects with a major depressive episode (see Results section). Specific activity for all subjects was at least 16 GBq/μmol. Following radiotracer injection, subjects underwent a dynamic PET acquisition protocol as described previously (Kortekaas et al. 2005).

PET procedure

All scans were performed with the use of an ECAT EXACT HR+ positron camera (Siemens/CTI, USA). After the radiotracer injection of $[^{11}C]$verapamil serial dynamic PET scanning was done at escalating time-frames and serial arterial blood sampling for $[^{11}C]$verapamil took place during the scan in order to define the input function. The samples of all subjects were collected with an automated sampling system, together with six manually drawn samples per subject. These samples (collected at 10-min intervals) were further processed to measure the radioactivity in plasma and blood. In this way the contribution of the injected activity to the PET signal could be calculated. No metabolite analysis was performed. Images were reconstructed in brain mode using an iterative reconstruction (ordered subsets – expectation maximization) with four iterations and 16 subsets and a Gaussian filter of 4 mm. The scans were performed in 3D mode.

Data analysis

The PET data were analysed with both a voxel-wise group analysis using statistical parametric mapping (SPM2, The Mathworks Inc., USA) and a ROI (regions of interest)-based approach. Results from both methods were used and compared.

First, all images were stereotaxically normalized to MNI space using SPM2 and a $[^{11}C]$verapamil template image that could be used from earlier studies of our group (Bartels et al. 2008a; Kortekaas et al. 2005). The resulting images were analysed with SPM2 as described below. For the ROI analysis the following ROIs, based on the literature as cited above, were selected for analysis: prefrontal cortex, anterior cingulate cortex, temporal lobes, amygdala and hippocampus. Therefore, predefined ROIs from the Anatomical Automated Labeling package (Tzourio-Mazoyer et al. 2002) were used to select the appropriate voxels and calculate the corresponding time-activity curves using in-house developed software. In addition, a whole brain ROI was manually drawn using Clinical Applications Programming Package software (CAPP; CTI/Siemens PET Systems, USA).

A graphical analysis according to Logan for quantification of the dynamic PET data was done with plasma data as input. The Logan plot was started at 5 min. With this method the distribution volume ($V_T$) was estimated. Because the slope (i.e. $V_T$ effect) obtained in the graphical approach may be biased in the presence of noisy data (Abi-Dargham et al. 2000), we verified the $V_T$ in a kinetic analysis (i.e. single tissue compartment model). The influx rate constant ($K_I$) and efflux $k_e$ were derived from this model and on all parameters (i.e. $V_T$, $K_I$ and $k_e$) the group means (patient group vs. control group) were compared with each other, using parametric tests. Analysis of covariance was performed in order to find relevant (clinical) predictors (age, length of present episode, number of previous episodes, severity of symptoms) of $V_T$ or $K_I$.

To exclude a possible confounding effect of subjects without a strict DSM-IV diagnosis of MDD, a sub-analysis was also done for the group with MDD only ($n=10$).

Data were then analysed with SPM2. To adjust for differences in individual neuroanatomy and to improve the signal-to-noise ratio, a 12-mm full-width at half-maximum Gaussian smoothing filter was applied to all images. We first compared the groups by looking at absolute differences in $V_T$, using $t$ test and ANCOVA with cofactors (MDR1 allelic variation, age, length of present episode, number of previous trials, severity of symptoms, injected activity of $[^{11}C]$verapamil). Clusters of $\geq 8$ voxels at a threshold of $p_{FDR}<0.05$ (false discovery rate) were considered to be significant. Coordinates were transformed into Talairach space (Talairach & Tournoix, 1988) using the mni2tal-transformation (http://www.mrc-cbu.cam.ac.uk/Imaging/).

Results

The mean injected $[^{11}C]$verapamil dose was not different for the two groups (control group: mean = 317 MBq, S.D. = 119; group with depression: mean = 279 MBq, S.D. = 179; $t$ test: $t = -0.344$; d.f. = 24; $p = 0.734$). Table 1 shows the demographic characteristics and medication use of the patient group. Twelve
patients had a previous depressive episode, three patients had a bipolar type I disorder, the current episode being depressive. Three subjects had a depressive episode with psychotic features. One patient was excluded from the analysis because the $V_T$ was considered an outlier, since the difference to the group mean was 4.6 times the standard deviation of the group for unknown reasons. The patient group [6 female/7 male, mean (±S.D.) age 54.1 ± 7.6 yr] was compared to a sex-matched comparison group (6 female and 7 male subjects; mean age 56.3 ± 14.3 yr). Patients had a mean score of 25.8 (±4.8) on the 17-item HAMD (range 19–37). Nine patients were currently depressed for >12 wk. Interestingly, seven of this group could be considered to be treatment resistant, using the criteria of Dunner (2006). Comorbid disorders included post-traumatic stress disorder (PTSD) ($n = 1$) and panic disorder ($n = 1$). All subjects used an antidepressant or a mood stabilizer at the time of scanning.

We determined three common MDR1 SNPs (−129 T>C (exon 1), 2677 G>T/A (exon 21) and 3435 C>T (exon 26)) in our patient group. For the SNP 3435 on exon 26 the allele frequencies in the patient group were CC 23%, CT 38% and TT 39%. The allele frequencies of SNP 3435 in our subjects were not different from the frequency in the population (Tan et al. 2004).

The mean brain time–activity curves (after correction for weight and injected dose) for the whole brain of patient and control groups were compared and the area under the curve (AUC) was calculated. No differences in the AUC were found. Both curves overlapped (data not shown). The $V_T$ values of the ROI (whole brain) were calculated with both the Logan analysis and the ‘single tissue compartment model’, in order to verify that the $V_T$ effect measured by the Logan method was concordant with another method. Pearson’s correlation coefficient ($r$) was very good, 1.000 ($p = 0.000$). The Logan curve gave an excellent fit

</table>
in all cases. The $V_T$ in ROI whole brain in the group of patients ($n=13$) with depression was lower at a nearly significant level ($Z=-2.008$, $p=0.055$). $K_1$ (whole brain ROI) showed no significant difference between the groups (values given are mean ± S.D.) [0.48 ± 0.15 (controls) vs. 0.41 ± 0.10 (patients), $p=0.15$]. Neither did the $k_2$ values [0.71 ± 0.10 (controls) vs. 0.75 ± 0.15 (patients), $p=0.46$]. In the ANCOVA none of the cofactors (age, length of present episode, number of previous episodes, severity of symptoms) showed a significant effect on the results.

Both groups were compared with a Student’s t test for the selected ROIs (prefrontal cortex, anterior cingulate cortex, temporal lobes, hippocampus, amygdala). Here we found a significantly lower $V_T$ in the patient group for the prefrontal cortex [0.64 ± 0.20 (controls) vs. 0.44 ± 0.15 (patients), $p=0.009$], the temporal lobes [0.66 ± 0.21 (controls) vs. 0.44 ± 0.19 (patients), $p=0.011$], the anterior cingulate cortex [0.53 ± 0.20 (controls) vs. 0.34 ± 0.18 (patients), $p=0.016$], and for amygdala [0.72 ± 0.30 (controls) vs. 0.49 ± 0.24 (patients), $p=0.045$] but not for hippocampus [0.55 ± 0.32 (controls) vs. 0.41 ± 0.13 (patients), $p=0.146$]. $V_T$ differences in prefrontal cortex and temporal lobes were significant after Bonferroni correction for multiple tests. $K_1$ and $k_2$ showed no differences between the groups for any of the ROIs. The mean ± S.D. of $V_T$ for each group are shown for each ROI in Fig. 1.

A pixel × pixel t test (without scaling) comparing both groups (13 vs. 13) in SPM2, showed several clusters, mainly located in temporal and frontal regions, in which the tracer uptake ($V_T$) was lower in the patient group, $p_{FDR}=0.028$ (see Table 2). The largest cluster measured 52 cm$^3$, including predominantly temporal lobes, reaching from the precentral gyrus to cerebellum and to the parietal lobes. The other large cluster (36 cm$^3$) included the prefrontal cortex (see Fig. 2). The clusters that reached statistical significance overlapped to a great extent with the areas found in the ROI analysis. Length of present episode (in weeks), HAMD scores, number of previous episodes, allelic variation of MDR-1 polymorphisms 3435C>T and 2677G>T, diagnosis and administered verapamil activity as covariates in ANCOVA had no significant effect as confounder on the results.

A subanalysis of the 10 patients with MDD was also performed. The subset was compared to a matched control group both at ROI level and in a voxel-wise analysis in SPM2. The results in the voxel-based approach indicated a somewhat stronger decrease in
V<sub>T</sub> compared to the control group. A large cluster (240 cm<sup>3</sup>, \( p_{\text{FDR}} = 0.016, t_{\text{max}} = 4.83 \)) was found, comprising mainly temporal lobes and frontal cortex (data not shown). The V<sub>T</sub> in ROI whole brain was also significantly lower than in the matched control group [0.75 ± 0.25 (controls) vs. 0.55 ± 0.08 (MDD), \( p = 0.030 \)]. The results for selected ROIs are shown in Fig. 1.

Finally, we compared the subgroup of patients with a treatment-resistant depressive episode (\( n = 7 \)) to a matched control group. This comparison gave comparable results in both approaches as the analysis of the whole group (\( n = 13 \)) did, yielding a significant decrease in V<sub>T</sub> both at ROI level and at voxel level in the group with a treatment-resistant depressive episode (data not shown).

**Discussion**

This study shows a significantly lowered [<sup>11</sup>C]verapamil uptake (V<sub>T</sub>) in prefrontal cortex and temporal lobes in patients with a major depressive episode. The results of different methods of analysis were all in accordance with each other.

In functional imaging studies the prefrontal cortex and temporal lobes have often been associated with MDD (Brody et al. 2001; Drevets, 2000). To our knowledge this is the first study showing involvement of P-gp in medicated patients with MDD.

Seven of the 13 patients studied were considered to be treatment resistant, most patients were admitted to a psychiatric hospital, indicating either a severe depressive episode or a chronic course of the illness. Although clinical parameters indicating treatment resistance or chronicity were not significant cofactors in ANCOVA, a significant decrease in V<sub>T</sub> (in temporal and frontal areas) was found in a subset of patients with a treatment-resistant depressive disorder (compared to a matched control group).

Treatment resistance in depression may in fact be associated with increased P-gp function. Increased P-gp function may cause low uptake of antidepressants. Similar to treatment-resistant epilepsy where increased expression of P-gp is associated with resistance to anti-epileptics and poor prognosis (Loscher & Potschka, 2002; Sisodiya et al. 2001), treatment resistance may also have influenced our results.

Regional differences in V<sub>T</sub> may reflect localized regions of higher P-gp function, which may be under the influence of a functional polymorphism of MDRI. The SNP C3435T has been associated with altered P-gp function, albeit in an intestinal cell line (Hoffmeyer et al. 2000), which does not necessarily reflect the P-gp expression in brain cells. However, the impact of genetic variations in the MDRI gene on the course of MDD or the response to antidepressants is considered to be moderate or absent, and results are conflicting (Eichelbaum et al. 2004; Laika et al. 2006; Mihaljevic-Peles et al. 2007; Qian et al. 2006; Woodahl & Ho, 2004). The frequencies of the determined polymorphism in our study group did not differ from the frequencies seen in the general population (Tan et al. 2004; Woodahl & Ho, 2004).
Our results may also be explained by a neuroinflammatory process. There is increasing evidence for the role of cytokines in the pathogenesis of depression. Inflammation results in the release of pro-inflammatory cytokines, acting as a neuromodulator and accounting for most of the symptoms in depression (Raison et al. 2006; Schiepers et al. 2005). Experimental animal models of inflammation show that inflammation can influence P-gp expression and activity in different ways (Fernandez et al. 2004; McRae et al. 2003; Monville et al. 2002). Although a decrease in function and expression of P-gp seems to be the case in acute inflammatory models, the study by Tan and colleagues shows that P-gp function was increased after the acute inflammatory phase (Tan et al. 2002). The course of a depressive episode may be similar in such a way that in the chronic phase P-gp is up-regulated. Post-mortem studies are warranted to confirm these hypotheses. It is desirable that further (neuroimaging) studies are conducted to shed light on the neuroinflammatory events in MDD.

Regional differences in \( V_T \) could be explained by an increase in atrophy in cortical brain areas in major depression. However, the most consistent findings in studies using structural MRI is reduction in hippocampal volume (Videbech & Ravndalde, 2004) and basal ganglia, whereas atrophy in frontal regions has been found less consistently. The most robust reduction in \( V_T \), in our study was seen in the temporal lobes. The fact that no differences in \( V_T \) were found in the hippocampus at ROI level may be due to spill-in of radioactivity of the adjacent choroid plexus, since it has been reported that there is a high accumulation of radioactivity in the choroid plexus (Langer et al. 2007).

A possible limitation of the present study is the fact that patients were treated with antidepressant medication. The increase in P-gp function in our study could be caused by the use of medication. Drugs or substances that are known to enhance P-gp expression were all excluded from our study (see Table 1). Many of the antidepressant and antipsychotic drugs used are substrates for P-gp, but their effect on P-gp activity is probably not clinically relevant (El Ela et al. 2004; Peer et al. 2004; Weber et al. 2005; Weiss et al. 2003a).

Several antidepressants and anticonvulsants are known to inhibit the P-gp pump in a concentration-dependent manner in porcine brain cells (Peer et al. 2004; Weber et al. 2005; Weiss et al. 2003a, b). In in-vitro studies of antipsychotics inhibition of P-gp was only seen in concentrations above therapeutically relevant plasma levels, thus suggesting that the inhibitory effect of antipsychotics may not play a role in clinical practice (El Ela et al. 2004; Weber et al. 2005). Recently, it was found that venlafaxine (used by three patients) can induce P-gp in human Caco-2 cells (Ehret et al. 2007). Nevertheless, the implication of chronic use of antidepressant and/or antipsychotic drugs is not known. It cannot be excluded that antidepressant and/or antipsychotic agents given for a sustained period lead to an up-regulation of the P-gp pump. To rule out this possibility, future studies in medication-naive patients are needed.

In addition to a possible effect on P-gp function, medication may also have influenced the metabolism of \([^{11}C]\)verapamil. It is known that anticonvulsants influence \([^{11}C]\)verapamil metabolism, probably through induction of cytochrome P450 (Abraham et al. 2008). Two of our patients were on valproic acid. However, leaving these two patients out of the analysis made no difference to the results. Medication may also have influenced the free fraction of \([^{11}C]\)verapamil, leading to a lower \( \text{VT} \) effect in the patient group. The influx parameter \((K_i)\) suggested no difference between the two groups, due to a large variance. The fact that only certain areas (i.e. temporal lobes and prefrontal cortex) showed a significant decrease in \( \text{VT} \) cannot be explained in this way.

In the present study no analysis of metabolites was performed. Although this can be seen as another limitation of the study, we assume that the total contribution of metabolites, that contribute to the PET signal, but have no affinity for the P-gp pump, is small. Only the N-demethylated fraction (so-called polar fraction) has no affinity for P-gp (Lubberink et al. 2007; Pauli-Magnus et al. 2000; Sasongko et al. 2005). As Lubberink et al. (2007) have shown the ‘one tissue compartment’ model gives an excellent fit of the data, irrespective of metabolite input. Their data indicate that the contribution of the polar fraction to the brain signal is small. However, it cannot be excluded that chronic use of antipsychotic and antidepressant agents may have influenced the metabolism of \([^{11}C]\)verapamil, thereby reducing brain uptake of the radiotracer in patients. However, the fact that a decrease in \( \text{VT} \) is only seen in specific areas can probably not be attributed to the metabolites of \([^{11}C]\)verapamil.

In summary, in our PET study using \([^{11}C]\)verapamil as a tracer, we have found evidence for an increased function of P-gp in patients with a major depressive episode under long-term treatment conditions, which for the first time may provide an explanation for treatment resistance in patients suffering from MDD.
