ABSTRACT

Background

Anthracyclines are frequently used chemotherapeutic agents for childhood cancer that can cause cardiotoxicity during and after treatment. Although several medical interventions in adults with symptomatic or asymptomatic cardiac dysfunction due to other causes are beneficial, it is not known if the same treatments are effective for childhood cancer patients and survivors with anthracycline-induced cardiotoxicity. This review is an update of a previously published Cochrane review.

Objectives

To compare the effect of medical interventions on anthracycline-induced cardiotoxicity in childhood cancer patients or survivors with the effect of placebo, other medical interventions, or no treatment.

Search methods

We searched the Cochrane Central Register of Controlled Trials (CENTRAL) (the Cochrane Library, 2015, Issue 8), MEDLINE/PubMed (1949 to September 2015), and EMBASE/Ovid (1980 to September 2015) for potentially relevant articles. In addition, we searched reference lists of relevant articles, conference proceedings of the International Society for Paediatric Oncology (SIOP), the American Society of Clinical Oncology (ASCO), the American Society of Hematology (ASH), the International Conference on Long-Term Complications of Treatment of Children & Adolescents for Cancer, and the European Symposium on Late Complications from Childhood Cancer (from 2005 to 2015), and ongoing trial databases (the ISRCTN Register, the National Institutes of Health (NIH) Register, and the trials register of the World Health Organization (WHO); all searched in September 2015).

Selection criteria

Randomised controlled trials (RCTs) or controlled clinical trials (CCTs) comparing the effectiveness of medical interventions to treat anthracycline-induced cardiotoxicity with either placebo, other medical interventions, or no treatment.
Data collection and analysis

Two review authors independently performed the study selection. One review author performed the data extraction and 'Risk of bias' assessments, which another review author checked. We performed analyses according to the guidelines in the Cochrane Handbook for Systematic Reviews of Interventions.

Main results

In the original version of the review we identified two RCTs; in this update we identified no additional studies. One trial (135 participants) compared enalapril with placebo in childhood cancer survivors with asymptomatic anthracycline-induced cardiac dysfunction. The other trial (68 participants) compared a two-week treatment of phosphocreatine with a control treatment (vitamin C, adenosine triphosphate, vitamin E, oral coenzyme Q10) in leukaemia patients with anthracycline-induced cardiotoxicity. Both studies had methodological limitations.

The RCT on enalapril showed no statistically significant differences in overall survival, mortality due to heart failure, development of clinical heart failure, and quality of life between treatment and control groups. A post-hoc analysis showed a decrease (that is improvement) in one measure of cardiac function (left ventricular end-systolic wall stress (LVESWS); -8.62% change) compared with placebo (+1.66% change) in the first year of treatment (P = 0.036), but not afterwards. Participants treated with enalapril had a higher risk of dizziness or hypotension (risk ratio 7.17, 95% confidence interval 1.71 to 30.17) and fatigue (Fisher's exact test, P = 0.013).

The RCT on phosphocreatine found no differences in overall survival, mortality due to heart failure, echocardiographic cardiac function, and adverse events between treatment and control groups.

Authors' conclusions

Only one trial evaluated the effect of enalapril in childhood cancer survivors with asymptomatic cardiac dysfunction. Although there is some evidence that enalapril temporarily improves one parameter of cardiac function (LVESWS), it is unclear whether it improves clinical outcomes. Enalapril was associated with a higher risk of dizziness or hypotension and fatigue. Clinicians should weigh the possible benefits with the known side effects of enalapril in childhood cancer survivors with asymptomatic anthracycline-induced cardiotoxicity.

Only one trial evaluated the effect of phosphocreatine in childhood cancer patients with anthracycline-induced cardiotoxicity. Limited data with a high risk of bias showed no significant difference between phosphocreatine and control treatments on echocardiographic function and clinical outcomes.

We did not identify any RCTs or CCTs studying other medical interventions for symptomatic or asymptomatic cardiotoxicity in childhood cancer patients or survivors.

High-quality studies should be performed.

**Plain Language Summary**

**Treatment for cardiac problems caused by anthracycline chemotherapy for childhood cancer**

Anthracyclines are anticancer drugs used in the treatment of different types of childhood cancer. An important adverse effect of anthracyclines is damage to the heart, which can lead to asymptomatic (without complaints) or symptomatic (with complaints) cardiac problems during and after cancer treatment. While there are several drugs available to treat other types of cardiac problems in adults, it is not known if these drugs are beneficial in treating cardiac problems caused by anthracyclines in childhood cancer patients and survivors. A physician confronted with a childhood cancer patient or survivor with anthracycline-induced cardiac problems should be able to make an informed decision on how to treat this patient based on high-quality evidence about the beneficial and adverse effects of the treatment options. We searched for and summarised studies that evaluated drugs for treating anthracycline-induced cardiac problems in childhood cancer patients and survivors.

We identified two randomised studies evaluating two different drugs in two different types of patients. One of these drugs, an angiotensin-converting enzyme (ACE) inhibitor (enalapril), had a short-term beneficial effect on heart function in survivors of childhood cancer with asymptomatic cardiac problems caused by anthracyclines compared with placebo. However, the drug had no significant beneficial effect on other important outcomes and was associated with side effects such as dizziness and fatigue. This study was of reasonable/good quality. The other study was of low quality and found no effect of a short treatment with phosphocreatine in childhood leukaemia patients with...
symptomatic or asymptomatic cardiac problems compared with a control treatment with vitamin C, adenosine triphosphate, vitamin E, and oral coenzyme Q10.

We could make no definitive conclusions about treatment options for anthracycline-induced cardiac problems in childhood cancer patients and survivors. High-quality studies are needed to determine if there are drugs that improve heart function in these patients.

BACKGROUND

Description of the condition

Anthracyclines are frequently used chemotherapeutics for childhood cancer that can cause serious cardiac dysfunction (Lefrak 1973; Van Dalen 2014; Von Hoff 1977). This so-called anthracycline-induced cardiotoxicity can develop during, or many years after, treatment and may present clinically, with symptoms of heart failure (Murooney 2009; Van der Pal 2012), or subclinically, with abnormalities found only in diagnostic tests (Ganame 2007; Lipshultz 1991; Van Dalen 2006a). It is estimated that almost 10% of childhood cancer patients treated with anthracycline doses of 300 mg/m² or more will eventually develop symptomatic cardiotoxicity, a condition that is associated with high morbidity and mortality (Steinherz 1995; Van Dalen 2006a). Asymptomatic signs of cardiotoxicity are found in up to 57% of survivors of childhood cancer and are often progressive over time, but the long-term prognosis of these abnormalities is not known (Kremer 2002; Lipshultz 2005a; Sorensen 2003). In the general adult population, individuals with asymptomatic cardiac dysfunction are at increased risk of developing symptomatic heart failure and death (Wang 2003). These findings raise the concern that children and young adults with asymptomatic cardiac dysfunction caused by anthracyclines are also at risk of progression to symptomatic heart failure in the long term.

Description of the intervention

Several cardiovascular drugs have been studied in people with cardiac dysfunction due to other causes. Studies in adults with symptomatic as well as asymptomatic heart failure due to causes other than anthracyclines have shown that treatment of an average duration of three years with angiotensin-converting enzyme (ACE) inhibitors reduces long-term morbidity and mortality, regardless of the aetiology of heart failure (Abdulla 2006; Garg 1995; Jong 2003; SOLVD 1991; SOLVD 1992). The Studies of Left Ventricular Dysfunction (SOLVD) also showed an improvement in quality of life in symptomatic participants and no negative effect in quality of life in asymptomatic participants (Rogers 1994; SOLVD 1991; SOLVD 1992). A cost-effectiveness study was performed in symptomatic SOLVD patients and showed survival benefit as well as cost savings (Glick 1995). Treatment with beta-blocking agents in addition to an ACE inhibitor improves the mortality outcome in people with symptomatic cardiac failure (CIBIS-II 1999; Foody 2002; Packer 1996a; Packer 1996b; Wägstein 1993), and improves cardiac function in people with asymptomatic heart failure (Colucci 2007; Exner 1999). Other medical interventions may also potentially improve the prognosis of people with symptomatic or asymptomatic heart failure, such as angiotensin receptor blockers (Granger 2003 and Maggioni 2002), or combinations of heart failure medications, such as angiotensin receptor blockers, ACE inhibitors, and beta-blockers (Cohn 2001; McMurray 2003).

Why it is important to do this review

Many collaborative groups have advocated screening for cardiac dysfunction in childhood cancer patients and survivors (Armenian 2014; Armenian 2015; COG 2006; Sieswerda 2012; SIGN 2013; Skinner 2005; Steinherz 1992). However, for appropriate screening for a disease, an effective treatment should be available (Wilson 1968). In addition, physicians who are confronted with childhood cancer patients and survivors with cardiac dysfunction should be able to make a well-informed decision regarding the risks and benefits of treatment options. The optimal treatment for people with anthracycline-induced cardiotoxicity, and how to decrease morbidity and mortality, are currently unclear (Lipshultz 2002; Silber 2004; Van Dalen 2003). Although medical interventions in populations with symptomatic and asymptomatic heart failure due to causes other than anthracyclines are beneficial, we cannot assume that the efficacy of this treatment is similar in childhood cancer patients and survivors (Kay 2001; Shaddy 2007). The different aetiology of the cardiac dysfunction, as well as the different age distribution, make it necessary to study the benefits and risks of treatment of symptomatic and asymptomatic anthracycline-induced cardiotoxicity in this specific population. Treatment of people with anthracycline-induced cardiotoxicity should ideally decrease morbidity and mortality, improve cardiac function, reverse disease progression, and improve quality of life.

This is an update of the first systematic review, Sieswerda 2011,
evaluating the current available evidence on medical interventions in both symptomatic and asymptomatic anthracycline-induced cardiotoxicity during and after treatment for childhood cancer.

OBJECTIVES
To compare the effect of medical interventions on anthracycline-induced cardiotoxicity in childhood cancer patients or survivors with the effect of placebo, other medical interventions, or no treatment.

METHODS
Criteria for considering studies for this review

Types of studies
Randomised controlled trials (RCTs) and controlled clinical trials (CCTs) (as defined by the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2008)), including non-inferiority and cross-over trials, comparing a medical intervention for treating anthracycline-induced cardiotoxicity with either placebo, other medical intervention(s), or no treatment.

Types of participants
Patients and survivors (previously) diagnosed with any type of childhood cancer (defined as a diagnosis of cancer at age 18 years or younger) and with symptomatic or asymptomatic anthracycline-induced cardiotoxicity. RCTs or CCTs including both children and adults were only eligible for inclusion in this review if the majority of participants were 18 years or younger at cancer diagnosis. Anthracycline-induced cardiotoxicity, as defined by the authors of the original study, could be diagnosed both during and after anthracycline treatment for childhood cancer. Due to the low number of patients expected, we did not exclude patients who also had been treated with mediastinal radiotherapy.

Types of interventions
Medical (that is drug) interventions given with the intention to change the course of anthracycline-induced symptomatic or asymptomatic cardiotoxicity. We excluded surgical interventions such as heart transplantation.

Types of outcome measures

Primary outcomes
1. Overall survival.
2. Mortality due to heart failure.
3. Development of clinical heart failure as defined by authors.
4. Occurrence of adverse events and tolerability as defined by authors.

Secondary outcomes
1. Change in cardiac function measured by different diagnostic tests as defined by authors.
2. (Duration of) hospitalisation for heart failure.
3. Change in NYHA (New York Heart Association) stage of heart failure (NYHA 1994).
4. Change in quality of life as defined by authors.
5. Costs as defined by authors.
Outcomes may have been assessed at any time during follow-up.

Search methods for identification of studies
Electronic searches
We searched the Cochrane Central Register of Controlled Trials (CENTRAL) (the Cochrane Library, 2015, Issue 8), MEDLINE/PubMed (1949 to 25 September 2015), and EMBASE/Ovid (1980 to 25 September 2015) for potentially relevant articles.

The search strategies for CENTRAL, MEDLINE/PubMed, and EMBASE/Ovid are shown in Appendix 1, Appendix 2, and Appendix 3. We used the highly sensitive search strategy for identifying reports of RCTs and CCTs (sensitivity-maximizing version) as described in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2008).

We scanned the ISRCTN Register (www.isrctn.com), the National Institutes of Health (NIH) Register (www.clinicaltrials.gov), and the trials register of the World Health Organization (WHO) (apps.who.int/trialsearch/) on 29 September 2015. The search keywords are shown in Appendix 4.

There were no language restrictions.

Searching other resources
We located information about trials not registered in CENTRAL, MEDLINE/PubMed, or EMBASE/Ovid, either published or unpublished, by searching the reference lists of relevant articles and review articles. In addition, we handsearched conference proceedings of the International Society for Paediatric Oncology (SIOP),
the American Society of Clinical Oncology (ASCO), the American Society of Hematology (ASH), the International Conference on Long-Term Complications of Treatment of Children & Adolescents for Cancer, and the European Symposium on Late Complications from Childhood Cancer from 2005 up to and including 2015. Again, there were no language restrictions. The search keywords are shown in Appendix 5.

**Data collection and analysis**

**Selection of studies**

After employing the search strategy described above, two review authors independently identified studies meeting the criteria for this review. We obtained in full any study which seemed to meet the inclusion criteria on the grounds of the title, abstract, or both for closer inspection. The review authors included or excluded studies for this review based on full-text assessment. Two studies selected for full-text evaluation were not in a language the authors were familiar with; for these, we contacted Cochrane collaborators from Russia and China, who individually determined if the studies were eligible. We recorded the reasons for exclusion of any study considered for the review. Discrepancies in the selection process were resolved between authors by consensus, or in case of doubt, by consulting a third-party arbitrator.

One review author performed the search of reference lists of relevant articles and review articles, as well as the search within the conference proceedings. We have constructed a flow diagram.

**Data extraction and management**

One review author performed data extraction using standardised forms, which a second review author checked. For the study published in Chinese, this was done by a review author from China based on full text and checked by another review author based on the abstract only. We abstracted information on the following items:

1. study design;
2. 'Risk of bias' items;
3. number of study participants;
4. participants, including:
   i) age at diagnosis;
   ii) age at study entry;
   iii) sex;
   iv) time since diagnosis;
   v) study performed during cancer treatment or in survivors;
6. outcome measures, including:
   i) outcome definition;
   ii) timing of outcome measurement;
7. length of follow-up.

In cases of disagreement, we re-examined the abstracts and articles and discussed the topic until consensus was achieved. No third-party arbitration was needed.

**Assessment of risk of bias in included studies**

One review author assessed the risk of bias using a standardised form, which was checked by another review author. The study published in Chinese was assessed by a review author from China based on full text and checked by another review author based on the (English) abstract only. We evaluated the studies according to the following criteria: generation of allocation sequence, concealment of treatment allocation, blinding of the study participants, blinding of personnel, blinding of outcome assessors, completeness of follow-up, intention-to-treat (ITT) analysis, selective outcome reporting, and other sources of bias. We determined the items blinding of outcome assessors, completeness of follow-up, and ITT analysis for all reported study outcomes. Only for overall survival, we regarded blinding of the outcome assessor not relevant. For all 'Risk of bias' items, we used definitions based on the module of Cochrane Childhood Cancer at the time our protocol was published (Module CCG), and on the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2008) (see additional Table 1). We resolved discrepancies between authors by consensus.
In case of doubt, we consulted a third-party arbitrator.

**Measures of treatment effect**

We related dichotomous outcomes to risk using the risk ratio (RR) and presented all results with the corresponding 95% confidence interval (CI). When only one study was available and there were no events in one of the treatment groups, it was not appropriate to calculate the RR, its 95% CI, and the corresponding P value. For these outcomes, we calculated the Fisher's exact P value instead, using PASW Statistics (SPSS) for Windows version 18 (SPSS Inc., Chicago, IL, USA). We planned to analyse continuous outcomes using the mean difference (MD). However, this was not possible since no standard deviation (SD) of change in the continuous outcomes was provided by the included studies. For the assessment of survival, we planned to use Parmar’s method if hazard ratios had not been explicitly presented in the study (Parmar 1998). However, this was not applicable, since we could not pool the included studies.

**Dealing with missing data**

When information relevant to study selection was missing, we attempted to contact the authors in order to obtain the missing data. We extracted data by allocated intervention, irrespective of compliance with the allocated intervention, in order to allow an ITT analysis. If this was not possible, we stated this and performed an as-treated analysis.

**Assessment of heterogeneity**

Assessing heterogeneity was not applicable, since we did not pool the included studies.

**Assessment of reporting biases**

We were not able to construct a funnel plot to evaluate the existence of publication bias graphically (Higgins 2008), since we included only two trials in this review and pooling of results was not possible. As a rule of thumb, tests for funnel plot asymmetry should be used only when there are at least 10 studies included in the meta-analysis. When there are fewer studies, the power of the tests is too low to distinguish chance from real asymmetry (Higgins 2008).

**Data synthesis**

We entered the data into RevMan 5.3 (RevMan 2014), and analysed according to the guidelines of the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2008). We used a random-effects model for the estimation of treatment effects throughout the review.

We included outcome measures in this systematic review only if it was the intention of the study authors to perform the necessary assessments in all randomised participants (that is not optional or only performed in some centres). When less than 50% of the participants in a study had an acceptable follow-up for a particular outcome measure, due to the associated high risk of attrition bias we did not report the results of this outcome measure.

We did not perform a pooled analysis since the included trials were not comparable with regard to important study characteristics, that is age, sex, cardiac dysfunction, treatment used, outcome definitions, and length of follow-up. We therefore summarised the results descriptively.

We planned to analyse data separately for clinical heart failure alone versus no clinical heart failure and for clinical and subclinical cardiotoxicity combined versus normal heart function. However, this was not applicable, since pooling was not possible and the study that included both participants with clinical and subclinical heart failure did not provide enough information to allow for such an analysis.

**Subgroup analysis and investigation of heterogeneity**

We hypothesised that treatment with mediastinal radiotherapy could cause other cardiac pathology, such as heart valve problems, and that it is therefore possible that treatment effects would differ between patients treated with and without mediastinal radiotherapy. However, we were not able to investigate this type of heterogeneity by performing a subgroup analysis with regard to previous mediastinal radiotherapy because pooling was not possible and because the individual studies did not provide outcomes separately for participants treated with and without previous radiotherapy.

**Sensitivity analysis**

Since we could not pool results, performing a sensitivity analysis using the ’Risk of bias’ criteria was not applicable.

**RESULTS**

**Description of studies**

**Results of the search**

Our original searches in the electronic databases CENTRAL, MEDLINE/PubMed, and EMBASE/Ovid identified 1429 titles with or without an abstract. In the update search of these electronic databases, we identified an additional 480 titles (442 records after removal of duplicates) (Figure 1), of which we selected eight references reporting on five studies for full-text assessment. No
additional reference in the update search was selected for full-text assessment. We did not include the remaining 1863 papers because they were not RCTs or CCTs, were laboratory studies, animal studies, did not include children with cancer or survivors of childhood cancer, or were preventive intervention studies of people without signs of cardiotoxicity. While examining the reference lists of relevant papers, we found an additional five papers, reporting on two studies (of which one was already identified in the electronic database search), which we also assessed in full text. We identified no new studies in the current update search. In total, we assessed the full text of 13 papers reporting on seven studies.
Based on full-text assessment, we finally included in this review seven papers reporting on two studies. We excluded six papers reporting on five studies. We have listed reasons for exclusion in the Characteristics of excluded studies table.

By scanning the conference proceedings of relevant conferences, we identified two papers that have not yet been published in full text and are awaiting further assessment (see the Characteristics of studies awaiting classification table). By scanning the ongoing trials databases, we identified one additional ongoing trial (see the Characteristics of ongoing studies table). We identified no additional studies in the current update search of conference proceedings and trials databases.

**Included studies**

We included two RCTs with a total of 203 participants in the review (Chen 2008; Silber 2004); we identified no new studies in the current update. Six papers provided information on one trial (see all references under Silber 2004). We extracted information about the study from all six papers.

In one trial, 69 participants received enalapril and 66 participants received placebo (Silber 2004). Participants were childhood cancer survivors with asymptomatic decline of cardiac function at some time during follow-up after anthracycline exposure. Follow-up time was a median of 2.80 (range 2 weeks to 6.1 years).

In the other trial, 35 participants received phosphocreatine and 33 participants received a control treatment with vitamin C, adenosine triphosphate (ATP), vitamin E, and oral coenzyme Q10 (Chen 2008). Participants were children with acute leukaemia and anthracycline-induced cardiotoxicity, part of which was symptomatic. The duration of treatment was 14 days, and assessment of cardiac function was performed one day after the end of treatment; it is unclear if there was longer follow-up, for example for the clinical outcomes.

For more information see the Characteristics of included studies table.

**Excluded studies**

The number of excluded papers based on full-text evaluation was six in total, reporting on five studies. A summary of the excluded studies can be found in the Characteristics of excluded studies table.

**Risk of bias in included studies**

We have summarised the evaluation of the risk of bias in the included studies below. An additional overview of evaluation in each domain per included study is provided in the Characteristics of included studies table (‘Risk of bias’ section) and summarised in Figure 2.
Allocation

In the enalapril study, allocation to treatment or control group was at random. For the allocation sequence, random permuted blocks with equal allocation were used within each stratum of prespecified variables (Silber 2004). Allocation was described as concealed, but the method of allocation concealment was not stated and was therefore unclear.

In the phosphocreatine study, allocation to treatment or control group was also at random, but the method used to generate the allocation sequence was not described (Chen 2008). It was not stated if there was allocation concealment.

Blinding

The enalapril trial was reported to be a double-blind study (Silber 2004). Although how the blinding was done was not clearly described, one of the additional papers concerning the trial stated that participants truly did not know which of the two treatments they had received (Silber 2004), indicating that blinding of participants was effective. It was also clearly stated that investigators were blinded to the intervention. However, it was not specified if the blinding of investigators concerned personnel as well as outcome assessors, if it was applicable to all studied outcomes, or if it was effective. Based on the effectiveness of blinding of participants and the statement that participants and investigators were blinded, we judged that this probably was the case. We consulted a third party regarding this judgement, who agreed with it.

In the phosphocreatine trial, blinding was not described and based on the different types of route of administration per treatment and control group, we judged that blinding of participants and personnel was very unlikely (Chen 2008). It was not stated if the investigators or outcome assessors were blinded, and we therefore we judged it to be unclear.
Incomplete outcome data

In the enalapril trial, follow-up was complete for overall survival, mortality due to heart failure, and development of clinical heart failure (Silber 2004). Follow-up was complete for change in cardiac function for the study outcomes maximal cardiac index (MCI) and left ventricular end-systolic wall stress (LVESWS), which were both measured in at least one post-baseline measurement in more than 80% of the participants. However, it should be noted that it was unclear if follow-up was complete for these parameters at the end of follow-up. For other measures of cardiac function (shortening fraction (SF) and stress-velocity index (SVI)) and the other outcomes that were reported (occurrence of adverse events and change in quality of life), it was unclear if the follow-up was complete. One of the additional papers concerning this trial stated that a considerable fraction of the study participants ended participation, but did not report exact numbers and timing of study dropouts (Silber 2004). It was clearly stated that intention-to-treat (ITT) analysis was performed for the trial’s primary and secondary outcomes. An extra per-protocol analysis was performed on LVESWS. For the other measures of cardiac function (SF and SVI) it was unclear if an ITT analysis was performed. For overall survival, mortality due to heart failure, development of clinical heart failure, change in quality of life, and occurrence of adverse events, ITT analysis was possible, since the treatment allocation was abstractable for the reported outcomes.

In the phosphocreatine trial, complete assessment was done for overall survival, mortality due to heart failure, and occurrence of adverse events (Chen 2008). For change in cardiac function, two parameters (echocardiography and hyper-sensitivity C-reactive protein (hsCRP)) were reported in all participants, while the other parameters of change in cardiac function outcomes (electrocardiogram (ECG), creatine kinase (CK), creatine kinase MB (CK-MB), lactate dehydrogenase (LDH1), and alpha hydroxybutyrate dehydrogenase (alphaHBDH)) were only assessed in some participants and therefore not reported in this review. For overall survival, mortality due to heart failure, two parameters of change in cardiac function (echocardiography and hsCRP), and the occurrence of adverse events, ITT analysis was possible, since the treatment allocation was abstractable for all reported outcomes.

Selective reporting

There was no sign of selective reporting in the enalapril trial (Silber 2004). A protocol was published that presented the outcomes that were planned to be studied as well as the planned data analyses (Silber 2004). All outcomes were reported and the analyses done in the final report (Silber 2004). The authors clearly explained that they performed some additional analyses based on exploration of the data.

In the phosphocreatine trial, there was no published protocol, and we therefore cannot exclude selective reporting bias in the study (Chen 2008).

Other potential sources of bias

In the enalapril trial, we were not aware of other potential issues that could put the study at a high risk of bias (Silber 2004). In the phosphocreatine study, we had concerns about the comparability of the study participants, especially with regard to potential confounders such as gender, age, cumulative anthracycline dose, type of anthracycline, other cardiotoxic treatment, number of symptomatic participants, and the provision of other treatments during the study (Chen 2008).

Effects of interventions

Both trials did not allow data extraction for all endpoints. See the Characteristics of included studies table for a more detailed description of the extractable endpoints of each study.

Overall survival and mortality due to heart failure

We could extract data on overall survival and mortality due to heart failure from both studies. In the enalapril trial, there were no deaths in both the intervention and the control group during the study (Silber 2004). However, one participant from the placebo group (1.5%) died eight months after the end of the study, as a result of congestive heart failure. As it was unclear if both the intervention group and placebo group had been followed beyond the end of the study, we did not calculate a risk ratio (RR) of death due to heart failure including this late death.

In the phosphocreatine trial, there were no deaths in both the intervention and the control group during the study (Chen 2008).

Development of clinical heart failure (as defined by authors)

The enalapril trial provided data on the occurrence of clinical heart failure, which the authors predefined as a clinically significant decline in cardiac performance (Silber 2004). In the intervention group, one participant (1%) developed such a significant decline, while in the control group this occurred in six (9%) participants (RR 0.16, 95% confidence interval (CI) 0.02 to 1.29; P = 0.09). See also Analysis 1.1 and Figure 3.
Occurrence of adverse events and tolerability (as defined by authors)

Both studies reported on the occurrence of adverse events. Neither study reported severity or grading.

In the enalapril trial, all participants were evaluated on the occurrence of adverse events (Silber 2004). The number of adverse events in participants was presented per adverse event, and many events were recorded (see Analysis 1.2 until Analysis 1.13 for RRs and corresponding 95% CI, and Table 2 for Fisher’s exact P values in outcomes with no event in one of the two groups). A notable difference in adverse events between groups was the higher occurrence of dizziness or hypotension (RR 7.17, 95% CI 1.71 to 30.17; P = 0.007; Analysis 1.2; Figure 4) and fatigue (Fisher’s exact test, P = 0.013; Table 2) in the enalapril group. Other reported adverse events were not statistically different between groups (Analysis 1.3 until Analysis 1.13, and Table 2).

In the phosphocreatine trial, all participants were also evaluated for adverse events (Chen 2008), however it was not stated what type of adverse events were assessed. No adverse events were found in participants of either the phosphocreatine group or the control group during the trial.

Change in cardiac function measured by a diagnostic test

Both studies provided several measures of change in cardiac function in the treatment and control groups.

The enalapril trial presented their results in unadjusted and adjusted linear mixed models of the change over time of MCI, LVESWS, SVI, and SF (Silber 2004). As the authors did not present dichotomous outcomes, we were unable to calculate RRs and therefore have described the outcomes as presented in the original study (reported as ITT analyses). All analyses were adjusted for anthracycline dose, age at diagnosis, follow-up time, gender, and cardiac irradiation. No differences were detected in the rate of change of all outcome parameters between intervention and control groups (adjusted model coefficient and P value of effect of enalapril: MCI 0.17, P = 0.36; LVESWS -1.41, P = 0.24; SVI 0.004, P = 0.68; SF 0.07, P = 0.81). After the data became available, the study authors explored the data and subsequently performed a piecewise linear model on LVESWS. In this per-protocol analysis (adjusted for the same covariates) they found that enalapril caused a decrease (that is improvement) in LVESWS (-8.62 g/cm² change) compared with placebo (+1.66 g/cm² change) in the first year of treatment (P = 0.036). After the first year there was no statistically significant difference in LVESWS change between enalapril and placebo groups (-0.30 versus +0.49 g/cm², P = 0.56).

In the phosphocreatine trial, complete baseline and outcome parameters were provided for echocardiographic cardiac function.
and the cardiac marker hsCRP (Chen 2008). All participants had normal echocardiograms before and at the end of treatment (not further specified). In the phosphocreatine group, mean (standard deviation (SD)) baseline levels of hsCRP were 8.79 (1.36) mg/L compared with 7.88 (2.08) mg/L in the control group, while post-treatment levels were 2.23 (0.82) mg/L in the phosphocreatine group compared with 4.2 (1.52) mg/L in the control group. Since the SDs of the difference before and after treatment within each group were not provided, we could not estimate the mean difference. It is therefore unclear if the change in hsCRP was significantly different between treatment groups. For the cardiac enzymes CK, CK-MB, LDH1, and alphaHBDH, only post treatment levels were provided and are therefore not presented in this review. For the outcomes ECG, troponin I and the combined outcome of all cardiac enzymes together (hsCRP, CK, CK-MB, LDH1, alphaHBDH, troponin I), numbers of participants with normal or abnormal outcomes after the intervention were only provided for those participants with abnormal values at baseline. Since these outcomes were only assessed in a specific subgroup of the studied cohort, we did not present them in this review.

(Duration of) hospitalisation for heart failure
None of the studies provided outcome data on the (duration of) hospitalisation for heart failure.

Change in NYHA (New York Heart Association) stage for heart failure
None of the studies provided change in NYHA stage for heart failure as an outcome parameter. The phosphocreatine trial did provide change in symptoms after the intervention for the participants with symptoms at baseline (Chen 2008). However, since this outcome was reported in less than 50% of the participants, we did not present these data in this review.

Change in quality of life (as defined by authors)
The enalapril study provided some information on quality of life (Silber 2004). There were no differences between groups on any of the dimensions of the Short-Form 36 General Health Survey or the Childhood Health Questionnaire-85. No further information was provided.

Costs as defined by authors
None of the included studies provided outcome data on costs.

DISCUSSION

As a result of survival rates of childhood cancer patients now approximating 75%, there is a steadily growing group of young childhood cancer survivors who are faced with asymptomatic or even symptomatic anthracycline-induced cardiac dysfunction. Many collaborative groups have advocated screening for cardiac dysfunction in childhood cancer patients and survivors (Armenian 2014; Armenian 2015; COG 2006; Sieswerda 2012; SIGN 2013; Skinner 2005). However, for appropriate screening for a disease, an effective treatment should be available (Wilson 1968). In addition, physicians who are confronted with childhood cancer patients and survivors with cardiac dysfunction should be able to make a well-informed decision regarding the risks and benefits of treatment options. Although ACE inhibitors and beta-blockers improve subclinical and clinical outcomes in adult populations with symptomatic and asymptomatic cardiac dysfunction due to other causes (Abdulla 2006; CIBIS-II 1999; Foody 2002; Garg 1995; Jong 2003; Packer 1996a; Packer 1996b; SOLVD 1991; Waagstein 1993), the different aetiology makes it difficult to extrapolate these beneficial effects to childhood cancer patients and survivors with anthracycline-induced cardiotoxicity. This is an update of the first systematic review, Sieswerda 2011, summarising all evidence on medical interventions for anthracycline-induced cardiotoxicity in childhood cancer patients and survivors.

For a reliable evaluation of the effects of medical interventions for the treatment of anthracycline-induced cardiotoxicity, the best study design is an RCT in which the only difference between the intervention and control group is the use of the medical intervention. However, because of the relative rareness of childhood cancer and therefore of survivors with cardiac dysfunction, we expected to find a low number of studies and therefore decided that both RCTs and CCTs were eligible for this review, keeping in mind the limitations of CCTs.

We identified two eligible RCTs investigating different medical interventions in different study populations and with different lengths of follow-up; in the update we identified no new studies. Since for both medical interventions only one study was available, we could make no definitive conclusions about their effects on anthracycline-induced cardiotoxicity. One RCT on enalapril in childhood cancer survivors with asymptomatic anthracycline-induced cardiotoxicity showed no significant effect of enalapril on overall survival, mortality due to heart failure, development of clinical heart failure, and quality of life compared with placebo (Silber 2004). Only a post-hoc, per-protocol analysis done by the study investigators themselves showed an improvement in a measure of cardiac function (LVESWS) in the enalapril group compared with the placebo group in the first year of treatment. No effect was found after one year for this or other echocardiographic parameters of cardiac function over time. Participants treated with enalapril had a higher risk of dizziness or hypotension and fatigue. We could make no conclusions about the effect of enalapril on (duration) of hospitalisation, change in NYHA stage of heart fail-
ure, and costs, since these outcomes were not studied. The other RCT, on phosphocreatine in children with acute leukaemia and symptomatic or asymptomatic anthracycline-induced cardiotoxicity, showed no significant differences in overall survival, mortality due to heart failure, echocardiographic cardiac function, and adverse events compared with a control treatment with vitamin C, ATP, vitamin E, and oral coenzyme Q10 (in all outcomes no events/abnormalities in both groups) (Chen 2008). The effect of the intervention on one marker (hsCRP) was unclear. The study did not report on development of clinical heart failure, (duration of) hospitalisation for heart failure, change in NYHA stage for heart failure, or costs. We could therefore draw no conclusions for these outcomes.

It should be noted that the reasons for not finding significant beneficial effects in the enalapril trial could be due to the low number of participants (that is low power) and participant compliance and loss to follow-up (Silber 2004). Also, the fact that there was a low threshold for patients to be classified as having anthracycline-induced cardiotoxicity could have influenced the identified effects of treatment. Patients with minor and sometimes temporary abnormalities were included, in which large benefits of the intervention were unlikely. In the SOLVD trial on enalapril in adults with asymptomatic cardiac dysfunction due to other causes than anthracyclines (SOLVD 1992), a clear benefit of enalapril was found on the occurrence of clinical heart failure. This trial had a much larger sample size (4228 participants) and used a more strict definition to classify patients as having cardiac dysfunction (that is a left ventricular ejection fraction (LVEF) of 35% or less). The enalapril trial had a relatively short length of follow-up (median 2.80 years). It is therefore unknown if there is a beneficial effect of enalapril in the longer term. In comparison, a follow-up study of the earlier mentioned SOLVD trial showed beneficial effects of enalapril treatment on mortality during a 12-year follow-up (Jong 2003; SOLVD 1992). In the phosphocreatine trial (Chen 2008), reasons for not identifying significant effects of the intervention could also be the low power and the very short duration of treatment and presumably also maximum follow-up (that is 14 days). Also, the most optimal dosage schedule of phosphocreatine is currently unknown. Suboptimal dosages of study treatment could have led to the finding of no differences between treatment groups.

The enalapril study had a low/moderate risk of bias (Silber 2004). There was a low/moderate risk of selection bias, performance bias, and detection bias. For most outcomes there was a low risk of attrition bias, but for some outcomes (the post-hoc analysis of LVESWS, other parameters of cardiac function (SF and SVI), change in quality of life, and risk of adverse events), ITT analysis was not possible or it was unclear if follow-up was complete, leading to a possible risk of attrition bias for these other outcomes. There were no other risks of bias, nor unexpected outcomes or inconsistencies in the data. The phosphocreatine study had a high risk of selection bias, performance bias, and detection bias. There was no sign of attrition bias. There was a risk of reporting bias, and we had concerns about the comparability of the two groups. We found no unexpected outcomes or other inconsistencies in the data.

The external validity of a study indicates how well the results of the study can be generalised to individual patients with anthracycline-induced cardiotoxicity during and after treatment for childhood cancer. Although we did not systematically assess this in this review, we regarded the external validity of the enalapril trial as reasonable (Silber 2004). Participant characteristics were well-defined, and the study population seemed to be a representative sample of childhood cancer survivors who can present with asymptomatic cardiotoxicity during follow-up. However, it should be noted that a large proportion of participants had been treated previously with cardiac radiotherapy. It is not unlikely that the pathophysiology, course, and response to treatment of cardiac dysfunction that is induced by both anthracyclines and radiotherapy is different from cardiac dysfunction caused by anthracyclines only. In addition, other study characteristics could have influenced the effects of treatment. An observational study in adults with anthracycline-induced cardiotoxicity suggested that time between the end of anthracycline treatment and start of heart failure treatment (including at least enalapril) influenced the chance of response to ACE inhibitors, with a longer follow-up time associated with a lower chance of a beneficial effect (Cardinale 2010). Another issue regarding the generalisability of the enalapril trial is that the diagnostic tools to determine cardiotoxicity that were used in this study are not easily used in daily practice. Especially equipment and expertise to determine MCI, LVESWS, and SVI may not be widely available in the follow-up settings of childhood cancer survivors. As previously mentioned, the duration of follow-up precludes extrapolation to follow-up longer than three years. Finally, clear outcome definitions were provided, making it easy to extrapolate the study outcomes to daily practice. The phosphocreatine trial was less well generalisable to daily practice (Chen 2008). Not all participant characteristics were described, including age and gender of the control group, time since leukaemia diagnosis, and information on (previous) cardiotoxic cancer treatment. No clear definitions (that is cutoff values of abnormal diagnostic tests) of cardiotoxicity were provided. No participant had an abnormal echocardiogram, and since most research on anthracycline-induced cardiotoxicity, as well as guidelines on detection of cardiotoxicity, include echocardiographic examination of childhood cancer patients and survivors, we feel that the study group is not very representative with regard to cardiotoxicity (COG 2006; SIGN 2013; Skinner 2005; Steinherz 1992; Van Dalen 2006b). In addition, phosphocreatine is an experimental therapy and not a registered agent at the European Medicines Agency (EMA) or US Food and Drug Administration (FDA). Both the intervention and the control treatments are not common practice in most countries. Treatment duration and outcome assessment of cardiac function
in this trial were only two weeks, so we only know the immediate effects of the intervention studied and not any long-term benefits or harms. Based on these arguments, we feel that the outcomes of the phosphocreatine trial can hardly be extrapolated to daily clinical practice and care for childhood cancer patients (Chen 2008).

There was no evidence available from RCTs or CCTs for other medical interventions for treating anthracycline-induced symptomatic and asymptomatic cardiotoxicity during and after treatment for childhood cancer (for a complete list of evaluated interventions, see the search strategy in Appendix 1; Appendix 2; Appendix 3).

Please note that in this review RCTs and CCTs were only eligible for inclusion when the participants (previously) had a type of childhood cancer (defined as a diagnosis of cancer at age 18 years or younger). RCTs or CCTs including both children and adults were only eligible for inclusion in this review if the majority of participants were 18 years or younger at cancer diagnosis. It is possible that there are RCTs or CCTs in adults that evaluate the effects of medical interventions on anthracycline-induced cardiotoxicity in cancer patients or survivors. We did not systematically search for trials in adults, but we noted that there was an RCT on enalapril for treating adults with evidence of cardiotoxicity (as indicated by elevated troponin I) after high-dose chemotherapy (which contained anthracycline in most participants) (Cardinale 2006). This trial found that participants treated with enalapril were significantly less likely to experience decline of left ventricular ejection fraction by 10% compared with untreated participants during one-year follow-up. There is another ongoing RCT of ranolazine for treatment of diastolic dysfunction in adults who completed standard dose chemotherapy for Hodgkin lymphoma, breast cancer, or colorectal cancer (Minotti 2013). However, this RCT is only aimed at short-term evaluation of cardiac function parameters and biomarkers and will unlikely inform the efficacy of ranolazine in long-term, patient-oriented outcomes such as mortality or cardiac events. There were also some non-controlled observational studies on adults with anthracycline-induced cardiotoxicity (Cardinale 2010; Jensen 1996; Jensen 2002; Noori 2000; Tallaj 2005; Thakur 2014; Vatutin 2001). One of these studies evaluated ACE inhibitor (with or without a beta-blocker) treatment in all study participants (Cardinale 2010). This study was a prospective cohort study with a mean follow-up of 36 months in 201 adults with symptomatic and asymptomatic cardiac dysfunction after anthracycline therapy, who were all treated with at least an ACE inhibitor as soon as cardiac impairment was noted. The study showed a (prespecified) response of cardiac function in 42%, a partial response in 13%, and no response in 45% of the study group. Responders had fewer cardiac events, and the study found a relationship between the duration of cardiac dysfunction and the probability of response to the therapy. The authors did not report if side effects occurred. It was concluded that beneficial effects of modern heart failure treatment are expected when treatment is started early after the detection of anthracycline-induced cardiotoxicity. It should be noted that it is not always appropriate to extrapolate adult cancer (survivor) studies to childhood cancer (survivor) studies. Other age ranges, pharmacokinetics, pharmacodynamics, as well as comorbidities and co-treatments may influence the effect of interventions for cardiotoxicity as well as the generalisability of studies to the clinical care of childhood cancer patients and survivors. Similarly, RCTs in other childhood populations are also difficult to generalise to childhood cancer patients and survivors. For example, in an RCT of the beta-blocker carvedilol in children with symptomatic heart failure (Shaddy 2007), almost 40% of the study population had symptomatic heart failure due to congenital heart disease, with often a very different anatomy of the heart.

Even though RCTs provide the highest levels of evidence, observational studies can sometimes be useful when no, or few, RCTs or CCTs are available. A retrospective cohort study described clinical and echocardiographic follow-up of 18 childhood cancer survivors with symptomatic and asymptomatic anthracycline-induced cardiotoxicity from the start of enalapril treatment during a median follow-up of 10 years (Lipshultz 2002). There were no serious side effects during the long-term enalapril treatment in the cohort. The authors found an initial improvement of cardiac function, but a deterioration of cardiac function and clinical parameters after six years of follow-up. However, the study was small, had no control group, and is highly prone to selection, detection, and performance bias. Another retrospective study of childhood cancer survivors treated with anthracyclines compared a group of 34 growth hormone (GH)-treated children to a group of 86 children not treated with GH therapy (Lipshultz 2005b). Echocardiographic assessments performed during routine clinical follow-up were re-analysed by an investigator blinded for the intervention. From repeated measurements analyses adjusted for baseline characteristics and non-random missingness of data, the authors’ main conclusion was that GH therapy increased left ventricular wall thickness during but not after therapy. It should be noted that among other issues, the retrospective construction of the control group, several confounding factors that were not adjusted for (such as co-treatment with cardiovascular medication), and missing outcome data for a large part of the two groups, put this study at high risk for selection and attrition bias. We can therefore draw no (careful) conclusions from these two observational studies.

We are awaiting the results of the ongoing study (NCT00003070), as well as more information from the two studies for which we could not obtain enough information for inclusion (see Characteristics of studies awaiting classification table). There was no new information about this ongoing study and two studies awaiting classification during the update of the review.

**Authors’ Conclusions**
Implications for practice

We identified one RCT comparing enalapril and placebo in childhood cancer survivors with asymptomatic cardiotoxicity (Silber 2004). Although there is some evidence that enalapril temporarily improves one parameter of cardiac function (LVESWS), the current evidence did not show a statistically significant improvement of other parameters of cardiac function or of clinical outcomes such as overall survival, mortality due to heart failure, occurrence of clinical heart failure, and quality of life. However, ‘no evidence of effect’ should not be confused with ‘evidence of no effect’. The RCT showed that enalapril treatment is associated with a higher risk of dizziness or hypotension and fatigue. Effects of enalapril on (duration of) hospitalisation, change in NYHA stage of heart failure, and costs were not studied. Also, no evidence was available on the effects of enalapril beyond 2.8 years of follow-up and on treating symptomatic cardiotoxicity. Based on the currently available evidence in childhood cancer survivors with asymptomatic anthracycline-induced cardiac dysfunction, we are not able to provide appropriate recommendations for clinical practice. Clinicians should weigh the potential benefits of enalapril with the known side effects in childhood cancer survivors with asymptomatic anthracycline-induced cardiac dysfunction.

We identified one RCT comparing phosphocreatine and a control treatment of vitamin C, ATP, vitamin E, and oral coenzyme Q10 in childhood leukaemia patients with symptomatic and asymptomatic cardiotoxicity (Chen 2008). Limited data with a high risk of bias and poor generalisability showed no difference of phosphocreatine compared with a control treatment on overall survival, mortality due to heart failure, echocardiographic function, and adverse events. The effect of the intervention on one marker (hsCRP) was unclear, and effects on occurrence of clinical heart failure, (duration of) hospitalisation, change in NYHA stage of heart failure, and costs were not studied. No evidence was available on the effects of phosphocreatine beyond two weeks of treatment or on the effects of phosphocreatine in survivors of childhood cancer with symptomatic or asymptomatic cardiotoxicity. Based on the currently available evidence, we do not recommend the use of phosphocreatine in clinical practice.

We identified no RCTs or CCTs studying other medical interventions for symptomatic or asymptomatic cardiotoxicity in childhood cancer patients or survivors. We can therefore make no conclusions about the effect of other medical interventions in these patients and are unable to provide appropriate recommendations for clinical practice.

Implications for research

One RCT has studied the effect of enalapril in childhood cancer survivors with asymptomatic anthracycline-induced cardiac dysfunction and found no clear effect on clinical outcomes, possibly due to, among other things, low power of the study (Silber 2004). As there is strong evidence that ACE inhibitors are beneficial for asymptomatic cardiac dysfunction in other populations, we urge the scientific community to start high-quality studies evaluating the effect of enalapril in childhood cancer patients and survivors with symptomatic or asymptomatic anthracycline-induced cardiotoxicity. These studies should preferably be RCTs, within homogenous populations and with long-term follow-up using valid and clinically relevant selection criteria and outcome definitions. Previous treatment with radiotherapy, duration since cancer diagnosis, duration of cardiotoxicity, the age of the patient, the severity of cardiotoxicity, and comorbidity should ideally be taken into account. The number of included participants should be sufficient for the power that is needed for reliable results. In addition, a long-term follow-up study of the enalapril trial (Silber 2004), evaluating the long-term effects of enalapril treatment versus placebo, would be very contributory to the current evidence.

One low-quality RCT has studied the effect of phosphocreatine in childhood leukaemia patients with symptomatic or asymptomatic anthracycline-induced cardiac dysfunction (Chen 2008). Other medical interventions for symptomatic or asymptomatic cardiotoxicity in childhood cancer patients or survivors have not been studied in RCTs or CCTs, even though several potentially beneficial treatment options are available. Evidence on potential treatments for this severe complication is especially needed for symptomatic childhood cancer patients and survivors, therefore, studies with the above-mentioned criteria should also be started evaluating different treatment options in childhood cancer patients and survivors with symptomatic cardiotoxicity.

ACKNOWLEDGEMENTS

We would like to thank the Editorial Base of Cochrane Childhood Cancer for their advice and support, Oleg Borisenko for translating a Russian article, Robert Shaddy, Charles Canter, and Daphne Hsu for providing additional information about a RCT, Joerg Meerpolh for providing information about one potential study awaiting classification, and Stichting Kinderen Kankervrij (KIKI), the Netherlands for the financial support which made performing this systematic review possible. Huib Caron was a coauthor of the protocol for this systematic review and the original version, and we thank him for his valuable input. The editorial base of Cochrane Childhood Cancer is funded by Kinderen Kankervrij (KIKI).

<td><strong>Participants</strong></td>
<td>68 childhood cancer patients, receiving phosphocreatine or control treatment of a combination of vitamin C, ATP, vitamin E, and coenzyme Q10. Included participants had anthracycline-related cardiotoxicity based on cardiac enzymes (CK, CK-MB, LDH1, alphaHBDH, troponin I, hsCRP), ECG and/or echocardiogram. Median (range) age of the phosphocreatine group was 5 (1 to 15) years; 15 of 35 were males. Age and gender of the control group were not mentioned. Median time since cancer diagnosis was not mentioned. Participants had a diagnosis of acute lymphatic leukaemia or acute myeloid leukaemia. For both groups information on (previous) cardiotoxic cancer treatment (cumulative anthracycline dose, cardiac radiotherapy and dose, and cardioprotective interventions) was not mentioned. Other cardiovascular comorbidities and treatments were also not mentioned. At the start of the study, distribution of abnormalities in cardiac symptoms and signs in the treatment group (n = 35) was: cardiac symptoms 18, abnormal cardiac enzymes 28, abnormal troponin I 7, abnormal ECG 20, and abnormal echocardiogram 0. Mean (SD) hsCRP in the treatment group was 8.79 (1.36) mg/L. For the control group (n = 33) this distribution was: cardiac symptoms 16, abnormal cardiac enzymes 25, abnormal troponin I 7, abnormal ECG 18, and abnormal echocardiogram 0. Mean (SD) hsCRP in the control group was 7.88 (2.08) mg/L. Time since diagnosis of cardiotoxicity was not mentioned.</td>
</tr>
<tr>
<td><strong>Interventions</strong></td>
<td>Phosphocreatine 1 g intravenously over 30 to 40 minutes once to twice per day (n = 35) or a combination treatment of vitamin C 150 mg/kg and ATP 20 mg into 5% glucose 100 ml intravenously once per day, oral vitamin E 50 mg once per day, and oral coenzyme Q10 (ubidecarenone) 10 mg 3 times per day. All treatment durations were 14 days.</td>
</tr>
<tr>
<td><strong>Outcomes</strong></td>
<td>Overall survival. Mortality due to heart failure (no definitions provided). Occurrence of adverse events (no definition provided). Change in cardiac function (normal/abnormal echocardiography, change in hsCRP, normal/abnormal ECG, normal/abnormal cardiac enzymes (CK, CK-MB, LDH1, alphaHBDH, troponin I, and hsCRP), postintervention levels of CK, CK-MB, LDH1, alphaHBDH, and troponin I. No definitions were provided)</td>
</tr>
<tr>
<td><strong>Notes</strong></td>
<td>The abstract (in English) mentions “retrospectively assessed”. However, we think the study is an RCT, because there is a statement in the methods section (in Chinese) that “all patients have entered the clinical trial with simple random allocation to treatment and control groups.” Duration of follow-up was not mentioned, but it seems that it was 15 days for the assessment of cardiac function, since that was done at the beginning and one day after the intervention. For clinical outcomes this was unclear. There was no loss to follow-up.</td>

<table>
<thead>
<tr>
<th>Methods</th>
<th>ACE inhibitor After Anthracycline (AAA) trial. Double-blinded RCT. Randomisations were performed using random permuted blocks (random size between 2 and 8) with equal allocation to each treatment (stratified according to the variables age at treatment (under 3 years old versus 3 years or older), total cumulative anthracycline dose (under 300 mg/m² versus 300 mg/m² or higher), and time from diagnosis (less than 10 years versus 10 years or more))</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>135 childhood cancer survivors (aged 8.3 to 30.6 years, 78 males) with asymptomatic decline of cardiac function at some time after anthracycline exposure, detected with echocardiography, resting or exercise GNA, MCI at peak exercise, and/or resting ECG. Median (range) time since cancer diagnosis 9 (4.2 to 22.3) years in the enalapril group and 9.6 (4.3 to 25.8) years in the placebo group. Participants had been treated for various...</td>
</tr>
</tbody>
</table>
types of cancer diagnosis at a median (range) age of 7.2 (3 to 21.8) years in the enalapril group and 8.2 (0.3 to 10.3) years in the placebo group. Median (range) age at study entry was 17 (8.3 to 31.5) years in enalapril group and 18.9 (8.1 to 30.6) years in placebo group.

Previous anthracycline treatment with median (range) cumulative anthracycline dose 305 (75 to 396) mg/m² in enalapril group and 300 (75 to 738) mg/m² in placebo group (types of anthracyclines not mentioned). Previous cardiac radiotherapy in enalapril group: 26 (38%), unknown in 1 (1.4%). In placebo group: 23 (35%), unknown in 0 (0%). Other previous potential cardiotoxic treatment or cardioprotective interventions not mentioned. Total radiotherapy dose, other cardiovascular comorbidities, and treatments were not mentioned. 1 participant in enalapril group required a growth hormone supplement and 1 participant in placebo group required a testosterone supplement.

At the start of the study, 111 participants had echocardiographic abnormalities (based on SF, LVESWS, and/or SVI) and/or abnormalities during resting or exercise GNA (based on EF). Of the remaining 24 participants, 7 had (only) abnormalities on cycle ergometry (based on MCI), and 17 had any of the abnormalities (possibly including an abnormal QTc interval on ECG) before study entry. Mean (SD) cardiac function in enalapril group was: MCI (L/min/m²): 8.39 (2.66) (68 participants), LVESWS (g/cm²): 73.2 (19.0) (69 participants), EF (%): 59.1 (7.4) (69 participants), SF (%): 30.7 (4.9) (69 participants), QTc (ms): 418 (23.4) (69 participants). Mean (SD) cardiac function in placebo group was: MCI (L/min/m²): 8.24 (2.57) (65 participants), LVESWS (g/cm²): 68.4 (20.4) (66 participants), EF (%): 58.3 (7.1) (64 participants), SF (%): 30.6 (3.9) (66 participants), QTc (ms): 411 (17.6) (66 participants). Time since diagnosis of cardiotoxicity was not mentioned.

Interventions

Oral enalapril once daily (n = 69) or oral placebo once daily (n = 66). Dosing of study medication was as follows: at start 0.05 mg/kg/day, escalation after 14 days to 0.10 mg/kg/day, and escalation at 3-months visit to 0.15 mg/kg/day if no side effects occurred.

Outcomes

Overall survival. Mortality due to heart failure (no definitions provided). Development of clinical heart failure (defined as a clinically significant decline in cardiac performance: documented acute congestive heart failure, SF decline 20% (and below 28%) from baseline in 2 measures or MCI decline by 30% (and 2 SD below the mean) from baseline in 2 measures). Occurrence of adverse events (no definition provided). Change in cardiac function (Primary outcome: rate of decline over time of MCI. Secondary outcome: rate of increase over time in LVESWS. Other outcomes: first-year reduction in LVESWS (post-hoc and ITT analysis), % change in SF and change in SVI over time) Quality of life: based on the Short-Form 36 General Health Survey (age above 14 years) or the Childhood Health Questionnaire-85 (age equal to or younger than 14 years). No definition for an abnormal outcome was provided

Notes

Median (range) follow-up time was 2.80 years (2 weeks to 6.1 years). Loss to follow-up was not mentioned. Since the authors did not present dichotomous outcomes, we were not able to define RRs for the outcome change in cardiac function; we have therefore described the outcomes.

### Characteristics of studies awaiting assessment [ordered by study ID]

#### Mandric 2008

<table>
<thead>
<tr>
<th>Methods</th>
<th>CCT comparing enalapril to placebo</th>
</tr>
</thead>
</table>
| Participants | 30 survivors of paediatric haematological malignancies, aged between 6 and 14 years and treated with doxorubicin. All participants had at least 1 cardiac abnormality identified at any time after anthracyclines exposure  
Enalapril group: 10 children, mean age at diagnosis 6 years, mean or median follow-up 16 months  
Placebo group: 20 children. Mean age and follow-up not mentioned  
Both groups had been treated with similar doses of anthracyclines. No further participant characteristics were provided.  
Duration of follow-up was unclear |
| Interventions | Enalapril (dose range between 0.2 and 0.5 mg/kg/day)  
Placebo (not further specified) |
| Outcomes | Cardiac evaluation (including echocardiography) at baseline and at 3, 6, 12, 16 months after initiation of enalapril/placebo therapy  
In the enalapril group, progressive improvement in LV dimensions (end-systolic and end-diastolic), fractional shortening, LV mass, LV per cent posterior wall thickening, interventricular per cent septal thickening, and Tei index was found  
In the placebo group, the same echocardiographic parameters were constant or worsened in the course of follow-up (not further specified) |
| Notes | This study has not been published in full text, but was presented at the SIOP conference 2008 (abstract L.030). It seems that children were not randomised. Completeness of follow-up was not mentioned |
**Mandric 2009**

<table>
<thead>
<tr>
<th>Methods</th>
<th>Unclear (possibly a CCT)</th>
</tr>
</thead>
</table>
| Participants | 27 children aged between 3 and 18 years  
Enalapril group: 10 children with subclinical cardiotoxicity on echocardiography  
No “cardioprotector” group: 6 children with a chemotherapeutic protocol completed. It was not specified if this group suffered from cardiotoxicity  
Newly diagnosed group: 11 children with newly diagnosed cancer. It was not specified if this group received an intervention  
No further participant characteristics were provided. Duration of follow-up was unclear |
| Interventions | Enalapril (not further specified)  
No “cardioprotector” (not further specified) |
| Outcomes | Periodic history and physical examination, electrocardiogram, chest X-ray, 2-dimensional/Doppler echocardiography, cardiac biomarkers (BNP, cTnI, ALAT, CPK)  
"Clinical manifestations": heart failure: 1 participant; “untypical manifestation”: 15 participants; "echocardiographic modifications": 6 participants; electrocardiographic changes: 5 participants; high values of plasma BNP (cutoff value of 100 microgram/ml): 11 participants  
The differences in these outcomes between subgroups were not mentioned, except that all children on “cardioprotector” treatment had normal values of BNP and cTnI |
| Notes | This study has not been published in full text, but was presented at the SIOP conference 2009 (abstract PQ.020). The title suggested that cardiotoxicity in children in the “no cardioprotector group” (and possibly also in the “newly diagnosed group”) was caused by anthracyclines. It seems that participants were not randomised. Completeness of follow-up was not mentioned |

ALAT: alanine transaminase  
BNP: brain natriuretic peptide  
CCT: controlled clinical trial  
CPK: creatine phosphokinase  
cTnI: cardiac troponin I  
LV: left ventricular  
SIOP: Société Internationale d’Oncologie Pédiatrique (International Society of Paediatric Oncology)

### Table 1. Criteria list for the assessment of risk of bias of included studies

<table>
<thead>
<tr>
<th>Item ID</th>
<th>Description</th>
<th>Implementation</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td><strong>Selection bias</strong></td>
<td></td>
</tr>
<tr>
<td>a</td>
<td>Was the allocation sequence adequately generated?</td>
<td>Adequate when a random (and therefore unpredictable) sequence was used to allocate the intervention to the participants</td>
</tr>
<tr>
<td>b</td>
<td>Was allocation adequately concealed?</td>
<td>Adequate when the upcoming allocations of participants were masked from those involved in enrolment into the trial</td>
</tr>
<tr>
<td></td>
<td><strong>Performance bias</strong></td>
<td></td>
</tr>
<tr>
<td>c</td>
<td>Was knowledge of the allocated intervention by participants adequately prevented during the study?</td>
<td>Adequate when the participants were unaware of the intervention they received</td>
</tr>
<tr>
<td>d</td>
<td>Was knowledge of the allocated intervention by personnel adequately prevented during the study?</td>
<td>Adequate when the personnel involved in the care of the participants were unaware of the intervention a participant received</td>
</tr>
<tr>
<td></td>
<td><strong>Detection bias (for each outcome separately)</strong></td>
<td></td>
</tr>
<tr>
<td>e</td>
<td>Was knowledge of the allocated intervention by the outcome assessor adequately prevented during the study?</td>
<td>Adequate when the outcome assessor was unaware of the intervention a participant received</td>
</tr>
<tr>
<td></td>
<td><strong>Attrition bias (for each outcome separately)</strong></td>
<td></td>
</tr>
<tr>
<td>f</td>
<td>Was the follow-up of the outcome complete?</td>
<td>Complete when the outcome was assessed in at least 80% of the study cohort</td>
</tr>
<tr>
<td>g</td>
<td>Was an intention-to-treat-analysis performed?</td>
<td>Adequate when all participants were analysed in the treatment group to which they were randomised, regardless of whether or not they received the allocated intervention</td>
</tr>
<tr>
<td></td>
<td><strong>Reporting bias</strong></td>
<td></td>
</tr>
<tr>
<td>h</td>
<td>Are reports of the study free of the suggestion of selective outcome reporting?</td>
<td>Adequate when a study protocol was available that prespecified study outcomes and analyses, which were all reported in the final study report</td>
</tr>
<tr>
<td></td>
<td><strong>Other sources of bias</strong></td>
<td></td>
</tr>
<tr>
<td>i</td>
<td>Was the study apparently free of other problems that could put it at a high risk of bias?</td>
<td>Adequate when there were no other important personal concerns about bias not addressed in the other domains in the tool</td>
</tr>
</tbody>
</table>

All items were scored yes, no, or unclear.

CONTRIBUTIONS OF AUTHORS

Daniel Cheuk performed the updated search, contributed to the interpretation of the results, and wrote and revised the manuscript.

Elske Sieswerda performed the updated search, contributed to the interpretation of the results, and critically reviewed the updated review.

Elvira van Dalen contributed to the interpretation of the results and reviewed the updated review.

Aleida Postma contributed to the interpretation of the results and critically reviewed the updated review.

Leontien Kremer contributed to the interpretation of the results and critically reviewed the updated review.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

As opposed to the protocol, which stated that we would use the criteria and definitions in the module of Cochrane Childhood Cancer (as available in 2008: Module CCG), we based the 'Risk of bias' assessment on both the earlier mentioned module and on information provided in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2008). We added new items (that is generation of allocation sequence, selective outcome reporting, and other sources of bias) and adjusted some definitions.

Based on a peer reviewer’s comment, we added to the methods section the Fisher’s exact test, P for situations in which only one study was available and there were no events in one of the treatment groups.

One review author performed the data extraction and 'Risk of bias' assessment of included studies, which another review author checked.

We did not contact authors in order to obtain missing data during the data extraction and 'Risk of bias' assessment.
INDEX TERMS

Medical Subject Headings (MeSH)

Adult Survivors of Child Adverse Events; Angiotensin-Converting Enzyme Inhibitors [adverse effects; *therapeutic use]; Anthracyclines [*administration & dosage; adverse effects]; Antibiotics, Antineoplastic [*adverse effects]; Cardiotonic Agents [*therapeutic use]; Enalapril [adverse effects; *therapeutic use]; Heart Failure [chemically induced; *drug therapy; mortality]; Neoplasms [drug therapy]; Phosphocreatine [*therapeutic use]; Randomized Controlled Trials as Topic

MeSH check words
