A B S T R A C T

Objective: Alterations in the microbiota composition of the gastro-intestinal tract are suspected to be involved in the etiopathogenesis of two closely related systemic inflammatory autoimmune diseases: primary Sjögren's syndrome (pSS) and systemic lupus erythematosus (SLE). Our objective was to assess whether alterations in gut and oral microbiota compositions are specific for pSS and SLE.

Methods: 16S ribosomal RNA gene sequencing was performed on fecal samples from 39 pSS patients, 30 SLE patients and 965 individuals from the general population, as well as on buccal swab and oral washing samples from the same pSS and SLE patients. Alpha-diversity, beta-diversity and relative abundance of individual bacteria were used as outcome measures. Multivariate analyses were performed to test associations between individual bacteria and disease phenotype, taking age, sex, body-mass index, proton-pump inhibitor use and sequencing-depth into account as possible confounding factors.

Results: Fecal microbiota composition from pSS and SLE patients differed significantly from population controls, but not between pSS and SLE. pSS and SLE patients were characterized by lower bacterial richness, lower Firmicutes/Bacteroidetes ratio and higher relative abundance of Bacteroides species in fecal samples compared with population controls. Oral microbiota composition differed significantly between pSS patients and SLE patients, which could partially be explained by oral dryness in pSS patients.

Conclusions: pSS and SLE patients share similar alterations in gut microbiota composition, distinguishing patients from individuals in the general population, while oral microbiota composition shows disease-specific differences between pSS and SLE patients.

1. Introduction

Primary Sjögren's syndrome (pSS) and systemic lupus erythematosus (SLE) are systemic inflammatory autoimmune diseases that share epidemiological, clinical, pathogenic and etiological features [1,2]. The world-wide prevalence rates for pSS and SLE are 0.01–0.09% and 0.02–0.24%, respectively, with a female:male ratio of 10:1 for both diseases [3–6]. pSS is characterized by chronic inflammation of the exocrine glands, in particular the salivary and lacrimal glands, resulting in oral and ocular dryness (sicca) complaints [7,8]. In SLE, a wide range of symptoms can be present, such as skin rash, photosensitivity, arthritis, glomerulonephritis, pericarditis, neurologic and hematological symptoms [2]. Overlap of clinical symptoms is frequently observed in pSS and SLE patients [7,9,10].

Host genetics and environmental factors are important etiological factors in pSS and SLE. pSS and SLE patients share genetic risk loci which predisposes individuals to these diseases. Genetic risk loci for both pSS and SLE include STAT4 and IRF5 (involved in innate immunity), IL12A and BLK (involved in adaptive immunity) and HLA class II region [11–14]. Many more genetic risk factors are currently known for SLE than for pSS [11]. The majority of SLE genetic risk factors are involved in innate immune signaling (e.g. TLR7 and TLR9) and lymphocyte signaling (e.g. IL-10, CD80) [15].

Despite increasing knowledge on genetic risk factors, still relatively little is known about environmental factors involved in the development of pSS and SLE. In this respect, the microbial composition in the gut and oral cavity may be important factors in the etiopathogenesis of these two chronic inflammatory autoimmune diseases [16–20]. Several
recent studies reported differences in gut and oral microbiota of pSS and SLE patients compared with healthy- and symptom-controls [17–19,21–24]. However, it is unknown whether gut and oral microbiota of pSS and SLE patients are truly specific for the disease, as there are no direct comparative studies including both diseases. Therefore, the aims of this study were to identify disease-specific differences in gut and oral microbiota of pSS and SLE patients and to assess whether pSS and SLE patients share overlapping signatures in gut microbiota composition. To address these questions, we performed 16S ribosomal RNA (rRNA) sequencing on fecal, buccal swab and oral washing samples from 39 pSS patients and 30 SLE patients that passed quality control. Fecal samples from 965 individuals from the general population, living in the same geographical area as pSS and SLE patients, were processed using the same pipeline and were used to assess shared signatures in pSS and SLE gut microbiota composition.

2. Patients and methods

2.1. Patients and methods

2.1.1. pSS and SLE patients

This study was approved by the Medical Ethical Committee (METc) of the University Medical Center Groningen (UMCG), Groningen, the Netherlands (METc 2015.472). All patients completed a written informed consent according to the declaration of Helsinki. Clinically diagnosted pSS patients (n = 40) and SLE patients (n = 35), living in one of the northern three provinces of the Netherlands, were consecutively selected for participation during a standard follow-up consultation at the UMCG Sjögren’s Expertise Center. The UMCG is a tertiary referral center for Sjögren’s syndrome (SS) and SS-associated mucosa associated lymphoid tissue (MALT) tumors. No selection based on race or ethnic background was made. Patients who had undergone abdominal surgery with (partial) bowel resection were not selected for participation.

All pSS patients fulfilled the 2016 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria [25]. All SLE patients fulfilled the 2012 Systemic Lupus International Collaborating Clinics (SLICC) classification criteria [26]. SLE patients using immunosuppressive drugs, other than hydroxychloroquine and low dose prednisolone (maximum of 7.5 mg daily), were excluded. Furthermore, SLE disease activity index (SLEDAI) was ≤4, in order to select disease controls with stable disease and low disease-activity. Routinely, when there is a clinical suspicion of secondary SS (e.g. sicca complaints), SLE patients are scheduled for a diagnostc workup in the Sjögren’s Expertise Center. This workup includes additional blood serology, functional tests of tear production (Schirmer’s test, ocular staining score), saliva production (unstimulated whole saliva) and a salivary gland biopsy. Each patient had to complete the Dutch Healthy Diet Food Frequency Questionnaire (DHD-FFQ) [27], the WHO Oral Health Questionnaire for Adults [28], the Xerostomia Inventory questionnaire [29] and the Rome III Diagnostic Questionnaire on irritable bowel syndrome (IBS) [30]. Demographic, clinical, biochemical and medication data were retrieved from standardized electronic medical records. Unstimulated (UWS) and stimulated (SWS) whole salivary flow rates in mL/min, routinely collected in pSS patients, were collected. Patients were required not to have used systemic antibiotics two months before stool and oral sampling.

2.1.2. General population controls

Population controls (n = 974) consisted of individuals participating in a population cohort study in the northern three provinces of the Netherlands, LifeLines DEEP [31,32]. In order to represent the general population as well as possible, population controls were not matched to pSS or SLE patients. Fecal samples and relevant phenotype data were available for 974 individuals. Individuals reported to use systemic antibiotics, anti-malarial or anti-fungal therapy were excluded (n = 9), leaving 965 population controls for analyses.

2.2. Methods

2.2.1. Fecal and oral sample collection and DNA isolation

Fecal and oral (i.e., buccal swab and oral washing) samples were collected from 40 pSS and 35 SLE patients. The required number of patients to include in this study was based on previous studies on the gut microbiome in rheumatoid arthritis (RA), pSS and SLE [18,21,33]. Fecal samples from the 965 population controls were previously collected (LifeLines DEEP) [31]. All fecal samples, from patients and population controls, were collected at home. pSS and SLE patients collected oral samples in the same week as fecal samples, before breakfast and oral hygiene activities. Directly after collection, samples were frozen by participants (i.e., patients and population controls) and stored in the participants’ home freezer. Within two weeks after sampling, a research assistant visited each participant to collect the fecal and oral samples. Samples were transported on dry ice to the hospital and stored at ~80 °C. DNA isolation on all fecal samples was performed exactly the same, using the AllPrep DNA/RNA Mini kit (Qiagen, Venlo, the Netherlands). DNA isolation on buccal swabs and oral washings was performed with the Ultraclean Microbial DNA isolation kit (MO BIO, Carlsbad, California, USA). See Supplementary methods for details.

2.2.2. 16S rRNA gene sequencing, quality control and taxonomy assignment

Illumina Miseq-v2 paired-end sequencing, covering the V4 variable region (Primers: 515F [GTGCCAGCMGGCGGTAA] and 806R [GGACTACHVGGGTWTCTAAT]), was performed the same on all fecal and oral samples using standardized sequencing techniques (see Supplementary Methods). Paired-end read alignment and quality control on samples from pSS and SLE patients was performed using Quantitative Insights Into Microbial Ecology (QIIME) v1.9.1 and for population controls with custom scripts [34], both with a minimum phred-quality score of 33. Rarefaction was performed at 8000 reads/sample for fecal samples and 5000 reads/sample for oral samples. Samples with lower number of reads/sample than these cut-offs were excluded.

The naïve Bayesian Ribosomal Database Project (RDP) Classifier was used to assign bacterial 16S rRNA sequences to genus level with SILVA128 as reference database [35,36]. Scripts on rarefaction and taxonomy assignment are available on https://github.com/alexa-kur/miQTL_cookbook. After taxonomy assignment, taxa observed only once in a sample and taxa with a relative abundance below 0.01% were removed.

Secondly, the ARB software environment (release 5.5) was used to gain more insight in species distribution [37]. ARB aligns 16S rRNA reads based on nucleotide sequence and secondary 16S rRNA gene structure information. To assign 16S rRNA reads to species level, a less stringent cut-off for read assignment was applied. Therefore, ARB was used as secondary taxonomy assignment method solely and not as primary discovery method.

2.2.3. Statistical analyses

QIIME was used to determine alpha-diversity (i.e., bacterial diversity within one sample) and beta-diversity (i.e., diversity in bacterial composition between samples). Alpha-diversity was assessed by Bray-Curtis distance matrix and visualized using principal coordinate analysis (PCoA). Adonis function from the vegan R-package was used to describe how much of the variation in Bray-Curtis distance could be explained by each phenotype, using 999 permutations and the R<sup>2</sup>-value as explanatory statistic.

R (version 3.3.1) was used for comparative statistics [38]. A Benjamini Hochberg false discovery rate (FDR) corrected p-value (q-value) was calculated for comparative tests. A q-value < 0.05 was used as cut-off for comparative statistical tests. Multivariate Association with Linear Models (MaAsLin, version 0.0.4) was used to find bacterial taxa

$^a$ pSS, primary Sjögren’s syndrome; SLE, systemic lupus erythematosus; Control, population controls; NA, not available; SD, standard deviation; ACR EULAR, American College of Rheumatology European League Against Rheumatism; SLICC, Systemic Lupus International Collaborating Clinics; MALT, mucosa-associated lymphoid tissue; RA, Rheumatoid Arthritis; ANA, antinuclear antibody; dsDNA, double-stranded DNA; ENA, extractable nuclear antigen; Ro/SSA, anti-Ro/Sjögren’s Syndrome autoantibody A; La/SSB, anti-La/Sjögren’s syndrome autoantibody B; C3/C4, complement C3/C4; IgG, Immunoglobulin G; NSAIDS, non-steroidal anti-inflammatory drugs; ESSPRI, EULAR Sjögren’s syndrome patient reported index; UWS/SWS, unstimulated/stimulated whole salivary flow; DHDF, Dutch healthy diet; FFQ, food frequency questionnaire.

$^b$ P-values for pSS and SLE statistical comparisons were calculated with the t-test or Fisher’s exact test. P-values for the overall study population were calculated with the one-way ANOVA or Chi-squared test.

$^c$ Clinically and serological SLE activity was clinically determined by the treating physician.

$^d$ Questionnaires were returned by 37/39 (95%) of pSS patients and 26/30 (87%) of SLE patients.

$^e$ Serum biochemistry was not available for population controls. A previous study showed that serum ANA (titer > 1:160) is positive in 6.1% of the general population and that anti-Ro/SSA, anti-La/SSB and anti-dsDNA is positive in 0.2-0.8% of the general population [66].

$^f$ DHDF-FFQ data was not available for population controls.
associated with pSS and SLE [39]. In MaAsLin, the following factors were taken into account as possible confounders in the taxa-phenotype association analyses: age, sex, body-mass index (BMI), smoking, diet (i.e., DHD-FQG score, only available for pSS and SLE patients), proton-pump inhibitor (PPI)-use and sequencing-depth [40,41]. A q-value < 0.10 was used as significance cut-off for taxa-phenotype associations.

3. Results

3.1. Characteristics of the study population

Demographic and clinical characteristics of the study groups are summarized in Table 1. After quality control, 39 fecal samples from pSS patients, 30 fecal samples from SLE patients, and 965 fecal samples from population controls were used in the analyses. SLE patients were slightly younger on average than pSS patients, corresponding to peak incidence ages for these diseases [3,4]. Eight out of 39 pSS patients (21%) had developed a mucosa associated lymphoid tissue (MALT) tumor in the course of the disease. Of the eight pSS patients with a history of MALT, seven patients either finished treatment more than one year before inclusion or were on a wait-and-see policy. Only one pSS patient with a MALT history received maintenance therapy with rituximab during the study. The vast majority of clinical characteristics was similar between pSS patients with and without a history of salivary gland MALT tumor (Supplementary Table 1). No differences were observed between pSS patients with and without a MALT tumor in the disease history, regarding the number of reads per fecal sample and the alpha- and beta-diversity of the gut microbiome.

Three pSS patients used immunosuppressive drugs during the study, of which two rituximab and one methotrexate. None of the pSS patients was treated with antimalarials. This is in accordance with a recent study showing that antimalarials are not effective in reducing symptoms in pSS-patients [42]. Instead, non-steroidal anti-inflammatory drugs (NSAIDs) were prescribed in 49% of pSS-patients, mainly because of arthralgia symptoms. SLE patients were mainly treated with antimarial therapy (83%). A full history of immunomodulating agents used by pSS and SLE patients, before inclusion in the study, can be found in Supplementary Table 2. PPIs were prescribed more often in SLE-patients (60%) than in pSS patients (33%) and in population controls (7%). To date, no studies are available that show a relation between antimalarial therapy and changes in the gut or oral microbiome. However, PPI-use can affect the gut microbiome [41] and was therefore included as possible confounder in our multivariate statistical model testing for disease-microbiota associations [39,41].

3.2. Alpha- and beta-diversity of the gut microbiome

Alpha-diversity measures of richness and diversity in fecal samples did not significantly differ between pSS and SLE (q = 0.35 and q = 0.93, respectively; Fig. 1A). Richness was significantly lower in samples from pSS and SLE patients compared with those from population controls (both q = 0.0004), but the within-sample diversity did not differ between pSS, SLE and population controls (both q = 0.7). Principal coordinate analysis (PCoA) of fecal samples from pSS and SLE patients showed no disease-specific clustering pattern (Fig. 1B). Disease phenotype (i.e., presence of pSS or SLE) did not significantly contribute to the variation in fecal bacterial composition between individuals (adonis, R² = 0.026, p = 0.07). In the PCoA including 965 population controls disease phenotype (i.e., presence of pSS, SLE or population control) explained 1.7% of the variation in fecal bacterial composition between individuals (adonis, q < 0.01; Fig. 1C). Other factors that were shown to contribute to the variation in fecal bacterial composition in the total study population were: age (explaining 1.6%, q = 0.01), sex (explaining 0.7%, q = 0.01), BMI (explaining 0.5%, q = 0.01), smoking (explaining 0.4%, q = 0.02), PPI-use (explaining 0.6%, q < 0.01) and NSAID-use (explaining 0.2%, q = 0.03) as analyzed by adonis. The overall gut microbiota composition of women from the general population was slightly more similar to that of pSS and SLE patients than that of men from the general population (Supplementary Fig. 1). This suggests that a small proportion of the difference in overall gut microbiota composition between pSS/SLE patients and population controls might be related to the higher percentage of males in the population control group (Table 1). In contrast, the gut microbiota composition of population controls with higher age, was slightly less similar to that of pSS and SLE patients (Supplementary Fig. 2). This indicates that the higher average age of pSS patients compared with the average age of population controls (Table 1) did not contribute to the observed difference in overall gut microbiota composition between pSS patients and population controls.

3.3. Individual gut bacteria associated with pSS and SLE compared to population controls

3.3.1. Lower Firmicutes/Bacteroidetes ratio in pSS and SLE patients

Profiles of the average bacterial composition at phylum and genus level in fecal samples were more similar between pSS and SLE than between patients and population controls (Fig. 2A). A lower ratio between phyla Firmicutes and Bacteroidetes has previously been observed in SLE patients compared to control subjects [21,22,43]. We also observed a lower Firmicutes/Bacteroidetes ratio in fecal samples from SLE patients compared to population controls (q < 0.001), but found a similarly lower Firmicutes/Bacteroidetes ratio in pSS patients compared with population controls (q < 0.001; Fig. 2B).

3.3.2. Individual bacterial taxa associated with pSS and SLE

Next, we assessed whether disease phenotype was associated with individual bacterial taxa (n = 152) using MaAsLin. The majority of genera associated with each disease, was shared between pSS and SLE patients compared with population controls (Fig. 2C, Supplementary Tables 3-5). Six genera showed significantly higher and twelve lower relative abundance in both pSS and SLE patients compared with population controls (q < 0.10, Fig. 2D). Although pSS and SLE were also associated with different taxa, none of these associations were significant when pSS and SLE patients were compared with each other (q > 0.10, Supplementary Table 6). Thus, difference in relative abundance of individual bacteria was much larger between pSS and SLE compared to population controls than the variation between the two diseases.

3.3.3. High relative abundance of Bacteroides species is characteristic for pSS and SLE, but not associated with Ro60/SSA-status

Phylum Bacteroides and genus Bacteroides relative abundance were most evidently higher in pSS and SLE patients compared with population controls (Fig. 2D). Also, genus Alistipes (belonging to Bac-
teroidetes) and phylum Proteobacteria showed evidently higher relative abundance in pSS and SLE patients compared with population controls. We subsequently analyzed which Bacteroides species were responsible for the higher relative abundance of genus Bacteroides in pSS and SLE patients, using the ARB software package [37]. The relative abundance of Bacteroides vulgatus, Bacteroides uniformis and Bac-
teroides ovatus was significantly higher in both pSS and SLE patients than in population controls (Wilcoxon, p < 0.01, q < 0.05; Fig. 2E; Supplementary Table 7). Bacteroides thetaotaomicron (B. theta) was significantly higher in SLE patients, but not in pSS patients compared to population controls (Wilcoxon, q = 0.03 and q = 0.17, respectively). Recently, cross-reactivity has been suggested between the gut com-
mensal B. theta and the Ro60-protein [43]. However, we did not ob-
serve a different relative abundance of B. theta in anti-Ro/SSA-positive pSS/SLE patients (n = 46) than in anti-Ro/SSA-negative patients (n = 22) (Supplementary Fig. 3). Neither did we observe associations between any other bacterial taxa and serum anti-Ro/SSA-autoantibody presence using the MaAsLin framework (Supplementary Table 8). Also,
anti-dsDNA and rheumatoid factor (RF) positivity was not associated with individual bacterial taxa \((q > 0.10)\), but anti-La/SSB-autoantibody positivity in pSS/SLE patients was associated with higher relative abundance of genus \textit{Clostridium sensu stricto} \((q = 0.05)\) (Supplementary Tables 9–11). However, this genus showed significantly lower relative abundance in pSS and SLE patients than in population controls (Fig. 2D), suggesting that higher \textit{Clostridium sensu stricto} relative abundance cannot directly be linked to positive anti-La/SSB autoantibody status.

### 3.4. Oral microbiota composition differs between pSS and SLE patients

#### 3.4.1. Significant differences in alpha- and beta-diversity

Study population characteristics of pSS and SLE patients used for oral microbiota analyses are summarized in Table 2. Buccal swab samples from 33 pSS patients and 34 SLE patients and oral washings from 34 pSS patients and 34 SLE patients passed quality control and were used in statistical analyses. Richness and diversity were significantly higher in buccal swabs and oral washings from SLE patients than in the same samples from pSS patients, with higher disease phenotype explaining 7.8–8.8% of the variation in oral microbiota composition. Other factors significantly contributing to the variation in oral microbiota composition included: number of own teeth (13.8%, \(q = 0.002\)), self-reported condition of gums (15.8%, \(q = 0.01\)), Xerostomia Inventory-score (9.8%, \(q = 0.002\)) and severity of oral dryness sensation (11.3%, \(q = 0.049\), adonis; Supplementary Fig. 4). These results indicate that oral dryness contributes more to oral microbiota composition than disease phenotype, which corresponds with our previous findings [23,24]. Smoking was not a factor affecting the overall oral microbiota composition in pSS and SLE patients (\(R^2 = 0.016, p = 0.4\), adonis).

#### 3.4.2. No individual taxa associated with disease-phenotype or Ro60/SSA-status

Profiles of the average bacterial composition at phylum and genus level in buccal swabs and oral washings showed disease specific patterns (Fig. 3D). However, no individual bacterial taxon in buccal swabs or oral washings was significantly associated with pSS or SLE (MaAsLin, \(q > 0.1\)). When all samples (i.e., one buccal swab and one oral washing from each patient) were included in the analysis, 36 taxa showed statistically significant differences in relative abundance (\(q < 0.10\), see Supplementary Table 12).

Previously, epitope mimicry between the oral species \textit{Capnocytophaga ochracea} and the Ro60/SSA protein has been reported [16]. However, we did not observe a difference in relative abundance of genus \textit{Capnocytophaga} in anti-Ro/SSA-positive patients (pSS and SLE patients together) compared with anti-Ro/SSA-negative patients (Supplementary Fig. 5). Neither did we observe associations between other taxa and anti-Ro/SSA-positive pSS/SLE patients in MaAsLin.

### 3.5. Connection between oral and gut microbiota

Recent clinical and experimental studies have suggested that...

correlation, tau = 0.35 and tau = 0.24, respectively) (Fig. 4D). Also, focal Actinomyces relative abundance correlated negatively with oral Lactobacillus relative abundance (q < 0.05, tau = −0.31). Furthermore, we observed higher Actinomyces relative abundance in both oral and fecal samples from SLE patients compared to samples from pSS patients (Fig. 4E). The difference in Lactobacillus relative abundance between diseases was significant in oral samples, but not in fecal samples. Together, these results suggest that specific oral microbiota can affect the gut microbiota composition.

4. Discussion

Alterations in gut and oral microbiota composition have previously been suggested as possible environmental factors in the etiology of pSS and SLE [16–19,21,43]. However, until now, it was unknown whether the gut and oral microbiome are specific for pSS and SLE or that these diseases share common characteristics in microbiota composition. Here we show that gut microbiota composition of pSS and SLE patients are very similar to each other but differ significantly from individuals in the general population. In contrast, oral microbiota composition differs between pSS and SLE patients.

Living-area, ethnic background, sex, age, technical variations, diet and medication use can influence the outcome of gut microbiota analyses [40,47–51]. Furthermore, ethnicity and living-area also influence the phenotypic expression of pSS and SLE patients [52–54]. In this study, we included pSS and SLE patients from the same geographical area and with a similar ethnic background as population controls. We showed that the strong female predisposition in pSS and SLE patients may have explained a small proportion of the difference in overall gut microbiota composition between pSS/SLE patients and population controls. However, the effect of age on the overall gut microbiome composition in the total study population was smaller and even opposed to the age-difference observed between pSS patients and population controls. Methods for fecal sampling, sequencing and taxonomy assignment were the same for pSS/SLE patients and population controls. Dutch-Healthy-Diet Food Frequency Questionnaire (DHD-FQF)-scores were not available for our general population cohort, but another Dutch population based study (i.e., Nutrition Questionnaires plus study, including randomly selected individuals from the central part of the Netherlands, aged 20–70 years, n = 1235) showed very similar DHD-FQF scores as in our pSS and SLE patient cohort [27].

None of the patients or population controls received antibiotic treatment at time of sampling. As expected, medication use differed between pSS/SLE patients and population controls. Also, the difference in use of antimarialars between pSS and SLE is not surprising, since antimarialar therapy has not been proven effective in pSS, but is a standard treatment for SLE [42,55]. Chloroquine and hydroxychloroquine have been reported to inhibit intracellular growth of bacteria in vitro, but these drugs do not seem to have any antibacterial activity or effect on extracellular bacterial growth [56,57]. Despite the difference in use of antimarialar therapy, no significant differences were observed in gut microbiota composition between pSS and SLE patients. This may indicate that antimarialar therapy has no significant effect on the gut microbiota composition. Only three pSS patients received treatment with immunomodulating agents during the study, of which two rituximab and one methotrexate. No evidence is available that rituximab has an effect on the oral or gut microbiome. No significant

increased relative abundance of oral bacteria in the gut may induce intestinal inflammation [34,44]. Local intestinal inflammation may subsequently predispose individuals to systemic inflammatory disorders, such as pSS and SLE [45,46]. Therefore, we assessed whether genera observed in oral samples from pSS and SLE patients were more prevalent and/or abundant in fecal samples from pSS and SLE patients than in fecal samples from population controls. The cumulative relative abundance of oral genera did not differ in fecal samples from pSS patients, SLE patients or population controls (Fig. 4A). Furthermore, none of the individual oral genera was more prevalent or abundant in fecal samples from pSS or SLE patients than in samples from population controls (Fig. 4B and C). However, Actinomyces presence and relative abundance was significantly lower in fecal samples from pSS patients than in those from population controls (q = 2.2×10^−9 and q = 4.1×10^−9, respectively). The relative abundance of Actinomyces and Lactobacillus in oral samples significantly correlated with their relative abundance in fecal samples (q < 0.05, Kendall's rank
associations were found between gut microbiota and methotrexate use in a recent study in the British TwinsUK cohort (a nation-wide registry of volunteer twins, n = 2737, 58% female, mean age 60 ± 12 SD, mean BMI 26 ± 5 SD) [49]. Regarding the use of NSAIDs, we found that NSAID use explained 0.2% of the overall gut microbiota composition in the total study population (i.e., patients and population controls, n = 1034), suggesting that NSAID use has a very small effect on the overall gut microbiota composition. In both the TwinsUK cohort (testing for topical NSAID use) [40], no significant effect of NSAIDs on the gut microbiome was observed. Also, oral corticosteroid use did not significantly affect the gut microbiome in these two large studies [40,49]. Thus, current evidence indicates that the effect of NSAIDs on the gut microbiome is absent or very small. In contrast, PPI use showed a stronger effect on the gut microbiome in both the LifeLines DEEP cohort (n = 1135, 58% female, mean age 45 range 18–81, mean BMI 25 range 17–49, testing for oral NSAID use) [40], as well as in the LifeLines DEEP cohort (n = 1135, 58% female, mean age 45 range 18–81, mean BMI 25 range 17–49, testing for oral NSAID use) [49] as well as in the LifeLines DEEP cohort (n = 1135, 58% female, mean age 45 range 18–81, mean BMI 25 range 17–49, testing for oral NSAID use) [49]. Together, these results suggest a connection between lower gut microbial richness and local and systemic inflammation. However, the sequence of events remains to be further investigated.

A lower Firmicutes/Bacteroidetes ratio has been observed before in pSS and SLE patients compared to population controls. Individuals with low richness in gut microbiota have higher inflammatory markers in blood (i.e., number of leucocytes and high-sensitivity C reactive protein) than in individuals with high richness [58]. Furthermore, in pSS patients, elevated levels of fecal calprotectin are observed, which suggests that low (grade) intestinal inflammation may be present in these patients [45]. Together, these results suggest a connection between lower gut microbial richness and local and systemic inflammation. However, the sequence of events remains to be further investigated.

Lower richness in gut microbiota composition was present in pSS and SLE patients compared to population controls. Fig. 4. Connection between oral genera observed in fecal samples. (A) Cumulative relative abundance of nine oral genera observed in fecal samples. Each line is one study subject. Boxplots summarize the cumulative relative abundance per group and correspond with the y-axis (Wilcoxon). (B) Presence of oral genera in fecal samples. Absence was defined as relative abundance < 0.0125%. Fisher's exact tests were performed on genera with an overall presence > 25%. (C) Relative abundance of oral genera in fecal samples. Blue asterisk indicates $q = 4.1 \times 10^{-8}$ for pSS vs population control (Wilcoxon). (D) Correlations between genera observed in oral and fecal samples. Relative abundances of buccal swab and oral washing samples were merged per individual. The color and size of the dots correspond with the strength of the correlation (Kendall's tau, $q < 0.05$). (E) Differences in Actinomyces and Lactobacillus relative abundance in oral and fecal samples from pSS and SLE patients (Wilcoxon). (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)
abundance in fecal samples, similar to the results reported by Grelting et al. [43]. Possibly, the low relative abundance of B. theta in fecal samples (< 1%) requires larger numbers of anti-Ro60/SSA-positive and –negative patients to detect a significant difference between these groups. To overcome this problem, quantitative microbiome profiling, in contrast to relative microbiome profiling, should be applied in future studies assessing the possible connections between B. theta, SLE and anti-Ro60/SSA autoantibodies [63]. Interestingly, B. theta relative abundance was significantly higher in SLE patients than in population controls. Thus B. theta may also be involved in SLE, independent of anti-Ro60/SSA autoantibody status.

The differences in oral microbiota composition between pSS and SLE patients are similar to what we previously observed between pSS patients and healthy controls, but also show new insights [23,24]. Previously, we did not observe differences in alpha-diversity between pSS patients and healthy controls in buccal swabs or oral washings, which suggests that the alpha-diversity of the oral microbiome in pSS patients is relatively normal [23,24]. Here we show that SLE is associated with a higher alpha-diversity in both buccal swabs and oral washings than in pSS patients. Higher alpha-diversity of the subgingival microbiome has previously been associated with periodontitis [64]. Furthermore, periodontitis prevalence is higher in SLE patients than in controls, while pSS patients do not have a higher risk of periodontitis [17,65]. Thus, although we did not clinically assess patients for periodontitis, higher alpha-diversity in SLE patients might be explained by a higher periodontitis prevalence in the SLE group.

In this study we confirm our previous observation that oral dryness explains more of the variation in oral microbiota composition than underlying disease [23,24]. Additionally, we show that self-reported number of own teeth and condition of gums explain large proportions (15% and 16%, respectively) of overall oral microbiota composition. This indicates that questionnaires on oral health can provide valuable information relevant to oral microbiome analyses.

The unique simultaneous sampling of the oral cavity and the gut allowed us to find correlations between oral and gut relative abundances of Actinomyces and Lactobacillus. This indicates that the oral microbiota composition influences that of the gut, supporting the idea that the oral cavity can serve as reservoir for potential pathobionts involved in intestinal inflammation [44]. Bacterial species- and strain-level identification is needed to further assess whether this oral-gut microbiota connection plays a role in intestinal dysbiosis and inflammation.

A limitation of this study is that the results were not replicated in an independent cohort, but our results confirm previously reported alterations in gut microbiota composition in SLE patients compared to (healthy) controls [21,22]. Furthermore, by including a large population control group, instead of healthy controls, we reduced the risk of introducing selection bias in assessing whether the gut microbiome is truly associated with a disease-phenotype.

The results of our study provide an important and solid basis for future studies on the role of the gut and oral microbiome in pSS and SLE. Elucidating the cause and effect relationship between the gut microbiome and pSS/SLE should be the main focus of future studies investigating the etiopathogenesis of pSS and SLE.

5. Conclusion

In conclusion, we show that pSS and SLE patients share a very similar gut microbiota composition that distinguishes patients from a large group of controls from the general population. The main characteristics of the gut microbiota composition in pSS and SLE patients are lower bacterial richness, lower Firmicutes/Bacteroidetes ratio and higher relative abundance of Bacteroides species. In contrast to the gut microbiota, the oral microbiota composition in pSS and SLE patients is determined by disease-related changes in the oral environment.

Conflicts of interest

No financial support or other benefits from commercial sources were received for this study. None of the authors have any financial interest that could potentially form a conflict of interest with regard to the work presented.
