Important insights into aging have been generated with the genetically tractable and short-lived budding yeast. However, it is still impossible today to continuously track cells by high-resolution microscopic imaging (e.g., fluorescent imaging) throughout their entire lifespan. Instead, the field still needs to rely on a 50-y-old laborious and time-consuming method to assess the lifespan of yeast cells and to isolate differentially aged cells for microscopic snapshots via manual dissection of daughter cells from the larger mother cell. Here, we are unique in achieving continuous and high-resolution microscopic imaging of the entire replicative lifespan of single yeast cells. Our microfluidic dissection platform features an optically prealigned single focal plane and an integrated array of soft elastomer-based micropads, used together to allow for trapping of mother cells, removal of daughter cells, monitoring gradual changes in aging, and unprecedented microscopic imaging of the whole aging process. Using the platform, we found remarkable age-associated changes in phenotypes (e.g., that cells can show strikingly differential cell and vacuole morphologies at the moment of their deaths), indicating substantial heterogeneity in cell aging and death. We envision the microfluidic dissection platform to become a major tool in aging research.

lifespan analysis | live-cell imaging | replicative aging | *Saccharomyces cerevisiae*

Aging is a complex gradual impairment of normal biological function caused by accumulation of molecular damage, finally culminating in death. Investigation of the genetically tractable and short-lived budding yeast *Saccharomyces cerevisiae* has yielded important insights into general eukaryotic aging: specific genes mediate aging (e.g. *SIR2*) (1–3) and dietary limitations can increase lifespan (4). *S. cerevisiae*'s replicative aging is considered an important model for aging in mitotically active cells (5, 6), with the replicative lifespan being defined as the number of daughter cells produced by a mother cell before the mother cell ceases dividing (Fig. 1A). Because of asymmetrical inheritance of damage to the mother (7), senescence factors are thought to accumulate in mother cells (8). Comprehensive analyses of age-associated phenotypes are considered to be instrumental in identifying the senescence factors (9, 10).

Analyzing the phenotype of replicative aging yeast cells, however, harbors a major technical challenge: continuous budding of the cells causes the original mother cells to be rapidly outnumbered by the exponentially increasing number of daughter cells, and thus makes long-term tracking of the aging cell impossible (Fig. S1). Technologies for studying age-associated phenotypes of replicative aging yeast cells are still very limited (e.g., ref. 11), and until today the prime tool in yeast aging research has been a 50-y-old dissection method (12), in which daughter cells are removed by microscopic micromanipulation with a needle from the larger mother cell on thick opaque culture pads (10, 13) (Fig. 1B). In a laborious and time-consuming manner—one lifespan experiment requiring several days of manual work for removing daughter cells after each mitotic cycle—such dissection allows assessment of the cell lifespan (10) or the isolation of single cells to generate microscopic

snapshots of differentially aged cells. This capability has, for example, led to the finding that the morphology of cells changes with age (9, 10, 12). However, because of several constraints, the conventional dissection method does not allow for high-resolution microscopic imaging (e.g., fluorescent imaging), and not for continuous tracking of cells throughout their complete lifespan, which would afford dynamic and essential insights into the phenotype of aging cells.

Unprecedented insights into single cells during aging would be possible with a method that allows for continuous high-resolution microscopic imaging of whole lifespans of yeast cells from their youth through senescence to death. The development of microfluidic devices has raised expectations for their capability to cultivate yeast cells in controlled environments with continuous microscopic observation (14, 15). Unfortunately, none of the currently existing microfluidic devices can be applied for long-term replicative aging studies. Respective devices are limited either by the number of generations over which mother cells can be monitored (typically eight) because of the exponential increase in the number of daughter cells retained in the microfluidic observation chambers (16–18), or by nonideal optical properties imposed by the chip design (19).

In this work, we set out to solve this problem and developed a microfluidic dissection platform with a prealigned single focal plane for long-term live-cell imaging of the complete replicative (and also chronological) lifespan of budding yeast cells. Similar to the classic dissection method, our platform also draws on the fact that the mother is larger than the bud cell (Fig. 1C). Yeast mother cells are trapped under soft elastomer (polydimethylsiloxane, PDMS)-micropad. A continuous medium flowing through the device washes away emerging buds and at the same time ensures a defined and constant environment during the whole aging experiment. This soft elastomer-based “microfluidic dissection platform” allows monitoring of the aging process of single cells from “young” to “death.” In addition to offering the capability of performing lifespan analyses in a less laborious manner, the excellent optical properties of the chip permit *in vivo* fluorescence measurements during the entire lifespan.

Author contributions: S.S.L. conceived the concept of microfluidic dissection and fabricated the microfluidic structure; S.S.L., L.P.L., and M.H. designed research; S.S.L., I.A.V., and D.H.E.W.H. performed research; S.S.L. and D.H.E.W.H. analyzed data; and S.S.L., I.A.V., and M.H. wrote the paper.

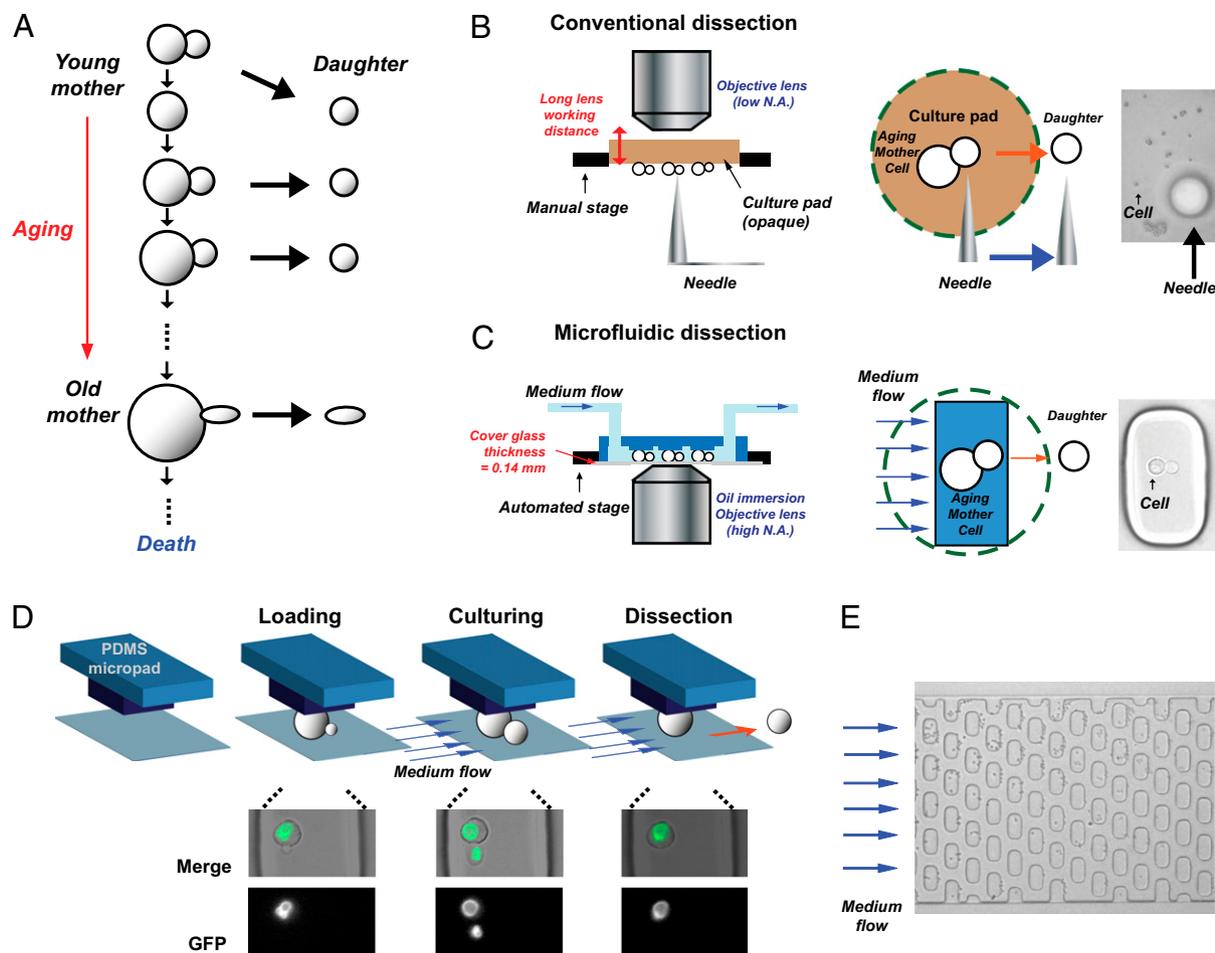

Fig. 1. Unique microfluidic method for monitoring the aging process of budding yeast. (A) Schematic illustration of replicative aging. The number of produced buds (daughters) represents the replicative age of the mother cell. Aged cells often increase in size and produce ellipsoidal daughters. (B) Schematic illustration of conventional dissection. A yeast daughter cell is manually removed by a dissection needle (indicated by arrow: typically approximately 10-times larger than cell) from the mother cell. The cells grow on a thick and opaque agar pad, which limits high-resolution microscopic imaging because of the required long-working distance of the objective lens. (C) Schematic illustration of microfluidic dissection. Mother yeast cells are held between a soft PDMS pad and thin cover glass ($4\ \mu\text{m}$ distance). This process allows high-resolution fluorescent imaging because high numerical aperture (high N.A.) objectives can be used. Daughter cells are continuously removed by flow of fresh media. (D) Principle of yeast cultivation and microfluidic dissection. Cell loading: Yeast cells are loaded under PDMS micropads. The elastic pads are slightly lifted by the hydrostatic pressure of the cell suspension during loading and hold the cells after a release of the pressure. Cell culturing: Fresh media is continuously provided through the array of micropads. The image shows the vacuole (green) during cell division. Dissection: The media flow (blue arrows) washes daughter cells from their mother cells because of the fact that the daughters' cell size is smaller than that of the mother cells. Cells expressing Vph1p-GFP served for visualizing the vacuoles. (E) Array of micropads. The chip contains 200 micropads arranged in an array format.

Results and Discussion

Yeast mother cells are trapped under micropads ($30\ \mu\text{m} \times 15\ \mu\text{m}$) (Fig. 1C and D) that are arranged in an array-based format (Fig. 1E). The engineered height of the micropad and the glass cover-slide is similar to the diameter of yeast cells (i.e., $4\text{--}5\ \mu\text{m}$), realizing a prealigned single focal plane for long-term live-cell imaging (Fig. 1C). Hydrostatic pressure, applied during the loading of the chip with cells (Fig. S2), lifts up the ~ 200 elastic PDMS micropads and allows the cells to pass beneath them. After the release of this pressure, cells are trapped underneath the pads (Fig. 1D, loading) without any detrimental effects on the cells (Fig. S3). After cell loading (described in detail in Fig. S2), a continuous medium flow through the device and (i) washes away emerging buds, which—because of their smaller size—are not held under the micropad (Fig. 1D: culturing, dissection) and (ii) ensures a defined and constant environment during the whole aging experiment. A stable and long-term operation of the chip ($> 5\ \text{d}$) is ensured by the overall chip's channel layout.

With this technology, it is possible to monitor, in a fully automated manner without intervention of the experimenter, ~ 50 single cells

from birth to death (i.e., up to about 60 generations) in a single experiment (Movie S1), despite the fact that occasionally bud cells push neighboring mother cells away from the micropad. This number of cells is comparable with the number of cells observed in conventional lifespan analysis (13). Fig. S4 shows the dynamics of the cell-retention capacity of the chip. We found that the division time of single cells obtained with our device agrees well with findings in another, independent study (20) ($71 \pm 0.8\ \text{min}$; $n = 206$ for first to third divisions of wild-type cells at 30°C in Synthetic Defined Media with the full amino acid complement), indicating that our setup allows for the generation of physiologically correct data. At this point, it is important to note that with our setup starting the experiment with newborn cells is not guaranteed, although considering the typical bud index distribution of an exponentially growing liquid culture (i.e., 80% of the cells have never budded before, 12% once, 6% twice, 3% three times) (21), the majority of loaded cells are still new or recently born cells.

We first asked whether we could use the device to generate classic lifespan data in a simpler and more automated way than with the

device consists of a main channel (height = 15 μm), which contains an array of micropads with a distance of 4 μm between the PDMS and glass slide, and a side channel (height = 100 μm) as a cell outlet during the loading process (Fig. S2). The microstructures were fabricated by photolithography using negative photoresists (SU-8 2002 and SU-8 10; Microchem). The side channel mold was made by adhesive tape. In a 1:10 wt/wt ratio, the PDMS base and curing agent were mixed, thoroughly stirred, and degassed in a vacuum chamber for 0.5–1 h to remove air bubbles. The degassed mixture was poured onto the SU-8 master mold and cured on a hot plate (65 $^{\circ}\text{C}$ for 1 h and 130 $^{\circ}\text{C}$ for 30 min). The cured PDMS was carefully peeled off the mold. Inlet and outlet connections per holes were punched using a blunt injection needle. Finally, the surfaces of a cover glass and the PDMS mold were subjected to UV irradiation (UV Ozone cleaner PSD-UVT; Novascan) for 6 min to activate the surface for covalent bonding. The mask design required to produce the devices will be made available upon request.

Live-Cell Imaging and Analysis. The microfluidic device was mounted on the stage of an inverted microscope (Eclipse Ti; Nikon Instruments) equipped with an incubator for cultivation at 30 $^{\circ}\text{C}$. Yeast cell growth and individual budding events were monitored by time-lapse imaging, successively capturing images every 10 min. The budding events are determined by comparison of two adjacent images, and the moment of cell death was identified by a sudden shrinkage of the cell's body. The hardware-based

focusing system (Nikon Instruments; Perfect Focus System) automatically and stably maintained the focus during the whole experiment. LED (pE2; CoolLed) illumination was used as the fluorescent light source. The images were taken with a high numerical aperture (N.A.) oil immersion objective lens (CFI Plan Apo 60 \times ; Nikon; N.A. = 1.4; working distance = 0.13 mm). The exposure times were 1 ms and 50 ms for transmission and GFP images, respectively. Defocused as well as focused transmission images were taken for subsequent segmentation of cells (28). The images were converted into binary images by manual application of the threshold function to ensure proper cell segmentation. The size of segmented cells was measured by the image process function in ImageJ (Wayne Rasband, National Institutes of Health, Bethesda, MD).

ACKNOWLEDGMENTS. The authors thank Matthias Peter and Uwe Sauer for generously allowing use of the microscope; Dino Di Carlo and Ralf Streichan for helpful discussions; Andreas Hierlemann for generously allowing use of the clean room facility; Reinhard Dechant, Alessandro Baldi, Annina Denoth, and Serge Pelet for helpful discussions and donation of the yeast strain; and Ida van der Klei, Liesbeth Veenhoff, and Yves Barral for excellent comments on the manuscript. This work was supported by an Interdisciplinary Pilot Project and the YeastX project within the Swiss Initiative in Systems Biology (SystemsX.ch), as well as by the NWO-funded Groningen Systems Biology Center for Energy Metabolism and Aging.
