Temperature and Electric Field Dependence of Spin Relaxation in Graphene on SrTiO$_3$

Si Chen,* Roald Ruiter, Vikramaditya Mathkar, Bart J. van Wees, and Tamalika Banerjee*

The theoretically predicted intrinsic spin relaxation time of up to 1 μs in graphene along with extremely high mobilities makes it a promising material in spintronics. Numerous experimental studies, however, find the spin lifetime in graphene to be several orders of magnitude below that theoretically predicted. Additionally, analyses of the spin relaxation mechanisms in graphene using conventional processes such as Elliot–Yaffet and D'yakonov–Perel' show a coexistence of both, with no clear dominance. Central to these experimental discrepancies is the role of the local environment including that of the underlying substrate. In this work, we use the electronically rich platform of SrTiO$_3$ with broken inversion symmetry and study spin transport in graphene in the presence of surface electric fields. We find spin relaxation time and length as large as 0.96 ± 0.03 ns and 4.1 ± 0.1 μm, respectively at 290 K in graphene, using non-local spin valve studies and find a non-monotonous dependence with temperature, unlike that observed in other substrates. Analysis of the temperature dependence indicates the role of surface electric dipoles and electric field driven electronic and structural phase transitions unique to SrTiO$_3$ for spin transport and spin relaxation in graphene.

Charge conduction and spin transport parameters in two-dimensional graphene are strongly influenced by extrinsic factors related to their local environment. Extrinsic influences range from the specifics of the underlying substrate (suspended, encapsulated, or high dielectric constant),[1,2] the quality of the contacts[3,4] to spin-orbit effects due to adatoms.[5–7] Despite significant improvements either on enhancing the graphene quality including encapsulation on an atomically flat two dimensional hexagonal Boron Nitride (hBN) substrate or by resolving extrinsic influences, the experimentally measured spin lifetime in graphene is orders of magnitude smaller than theoretically predicted.[8–11] Furthermore, conventional spin relaxation mechanisms such as Elliot–Yaffet and D'yakonov–Perel' fall to unambiguously explain the nature and dominance of the spin dephasing processes in graphene on different substrates.[8–14] Spin dephasing can originate from a multitude of effects such as flexural distortions, ripples, local magnetic moments, to name a few, but understanding of their precise microscopic mechanism still remains elusive.[5–7]

In this context SrTiO$_3$ (STO) lends itself as an interesting choice of substrate to study spin relaxation mechanisms in graphene.[15] STO has an atomically flat surface, similar to that of hBN, with roughness of 90–150 pm and no dangling bonds. However, unlike hBN, STO is electronically versatile. This stems from the remarkably large dielectric constant ($\varepsilon_r$) of 300 at room temperature that increases non-linearly to $>20,000$ at 4 K.[16] Further, distinct from most other substrates on which charge and spin transport in graphene has been studied, the broken inversion symmetry at the surface of STO leads to Rashba spin orbit fields that can be tuned by an electric field.[17] Recently it was demonstrated that electric dipoles, formed at the surface of STO, results in a large out of plane electric polarization that influences the charge transport in graphene.[18] STO undergoes a ferroelastic transition changing from cubic ($a = 3.905$ Å) to tetragonal symmetry ($c/a = 1.0056$) at $T = 105$ K.[19] This is accompanied by structural domains that can be moved with an external gate-bias.[20,21] The movement of such structural ferroelastic domains at low temperatures can lead to modulations in the surface potential in STO that causes local fluctuations in the carrier density of graphene. Thus STO offers an electronically rich transport platform for graphene-based devices. Recent studies on the charge transport in graphene on STO[22–28] discusses the influence of the high $\varepsilon_r$ and its role in screening impurities and improving the charge mobility, $\mu$, in graphene.[29]

Interestingly, in spite of the above studies, the influence of temperature and electric field driven structural and electronic phase transition in STO, as well as the large intrinsic Rashba spin orbit fields, on spin transport in graphene is largely unexplored. In this work, we study spin transport in graphene on STO for the first time and investigate the effects of temperature and electric field using spin injection contacts of Co/AlO$_x$. We find the spin relaxation time at 290 K to be as long as $0.96 ± 0.03$ ns, with a spin relaxation length of $4.1 ± 0.1$ μm.
To investigate the role of the surface dipoles and the large, temperature dependent, non-linear dielectric constant on spin transport in graphene and across the ferroelastic transition in STO, spin transport measurements are performed at different temperatures. A non monotonous temperature dependence of spin transport parameters, characterized by spin lifetime and diffusion constant is observed. We find the spin transport parameters to be lower at 4 than at 290 K – contrary to that expected and an observation not reported earlier using other substrates such as SiC or SiO2. Furthermore, we find that the gate dependence of the spin relaxation parameters at 4 K is associated with the modulation of the strength of surface dipoles in STO. An analysis of the spin relaxation mechanisms reveals the coexistence of both Elliot–Yaffet and D’yakonov–Perel’ scattering processes.

To investigate spin transport in graphene on STO, lateral spin valves of exfoliated graphene on TiO2 terminated STO were fabricated. One side polished STO (100) substrates (Crystec GmbH) were treated with a standard protocol\cite{30, 31} to achieve a TiO2 terminated surface. An atomic force microscope (AFM) scan of one such terminated STO surface is shown in Figure 1a. Graphite (grade ZYA) was exfoliated on a clean SiO2/Si wafer and single layer graphene was selected based on optical contrast. These flakes were transferred from the SiO2 to the desired area on the STO substrate using a polycarbonate dry pick-up technique.\cite{32} Polycarbonate residues left behind after the transfer were removed by treating the substrate at 50°C with chloroform for a period of several hours to days. Electrical contacts were defined using electron beam lithography and deposited using electron beam evaporation in multiple steps. A tunnel barrier was deposited in a two-step process: first 0.4 nm of aluminium was deposited and oxidized for 10 min in a pure oxygen atmosphere. This step was repeated once more to obtain a ~1 nm thick AlOx tunnel barrier. Thereafter 35 nm of ferromagnetic cobalt was deposited and capped with 5 nm aluminum layer to prevent cobalt from oxidizing. The substrate was bonded on a chip carrier using silver paste, which serves as the back gate during our transport measurements. An optical image of the device is shown in Figure 1b.

Spin transport measurements were performed on the device, using a non-local geometry. This geometry, shown in Figure 1c, separates the charge current path from the voltage contacts thus excluding spurious signals. The center to center separation between contacts 2 and 3 is 4.8 μm. In this configuration both spin valve as well as Hanle precession measurements can be performed. Assuming $\alpha$ in STO to be 24 000, we calculate the mobility $\mu$ of the sample to be 658 cm²/Vs at 4 K obtained using $\mu = 1/\alpha e d$. Spin valve measurements were performed by sweeping an in-plane magnetic field $B$ in the y-direction and measuring the non-local resistance $R_{NL} = V/I$, using lock-in techniques with frequencies <15 Hz.\cite{33} Figures 1d,e show the response of one of the non-local spin valves at 4 and 290 K respectively. Three clear switches are present at both temperatures, corresponding to contacts 1, 3, and 2.

Additionally temperature dependent Hanle precession measurements were performed and shown in Figures 2a,b,d,e, are for different temperatures and magnetic configurations of the electrodes $\uparrow \downarrow \uparrow$, $\uparrow \downarrow \uparrow \uparrow$, and $\uparrow \uparrow \uparrow \downarrow$ for the contacts 1, 2, 3 ($\downarrow$ refers to the magnetization of the electrodes in y and $-$y direction, respectively). The B-field is swept out-of-plane (z-direction) while measuring $R_{NL}$. Spins injected at contact 3 will start to precess around the B-field, thereby changing the projected spin component along the y-direction where they are detected by contacts 1-2. The resultant Hanle curves of $\uparrow \uparrow \downarrow \downarrow$, $\uparrow \downarrow \uparrow \uparrow$, and $\uparrow \uparrow \uparrow \uparrow$ configurations are shown in the top panels in Figures 2a,b,d,e (black, red, and purple curves, respectively). A common background is subtracted to obtain the pure spin signal using: $R_{NL} = 1/2 (R_{\uparrow \downarrow \uparrow \uparrow} - R_{\uparrow \uparrow \uparrow \uparrow})$ as detailed in ref. [8]. The blue curve in the bottom panel in Figures 2a,b,d,e is the data after background subtraction. Thereafter, it was fitted with the steady state solution to the Bloch equation in the diffusive regime.\cite{33, 34} From this, the spin diffusion constant $D_s$ and the spin relaxation time $\tau_s$ were obtained and the spin relaxation length was calculated using: $\lambda_s = \sqrt{D_s \tau_s}$. From the fitting, we find $\tau_s = 0.96 \pm 0.03$ ns, $D_s = 0.02 \pm 0.001$ cm²/s⁻¹, and $\lambda_s = 4.1 \pm 0.1$ μm at 290 K. The extracted values at other temperature can be found in the bottom panel of Figures 2a,b,d,e.

We find that the value at 290 K compares well to that reported on hBN substrate,\cite{8} however temperature dependence studies were not...
reported by those authors. Our findings establishes the effectiveness of STO as a suitable platform to study spin transport in graphene on STO.

In order to investigate the influence of temperature driven electronic and structural phase transitions in STO on spin transport in graphene, we exploit the temperature dependent Hanle measurements. Before starting the spin transport measurements, a back gate was swept between 0 V to 70 V at 4 K in order to characterize the charge transport properties in graphene on STO (see Figure S2, Supporting Information). Thereafter spin transport measurements were carried out while heating up the device. Typically the measurements were recorded after $R_{sq}$, the square resistance of graphene, stabilized over time. The measurements were performed using the non-local geometry (Figure 2c) in a temperature range between 4 and 290 K. A non monotonous variation of the spin relaxation time, $\tau_s$, with temperature is observed up to 180 K which decreases thereafter with increasing temperature as shown in (Figure 3a–c). The variation of the spin diffusion constant, $D_s$, with temperature is different from that of the spin relaxation time as shown in Figure 3b. The calculated value of the spin relaxation length, $\lambda_s$, shows a maximum 7 µm at 180 K. We have observed similar trends in the temperature dependence of spin transport, but with a shorter spin relaxation time, on devices fabricated on other STO substrates.

The spin transport parameters are usually known to decrease with increasing temperature, due to electron-phonon scattering. Temperature dependent studies of spin transport parameters in graphene are scarce and two earlier studies[3,4] on SiC and Si substrate report a decrease of spin transport parameters with increasing temperature. This is ascribed to the enhanced electron-phonon scattering at higher temperatures. Although we find a similar trend for temperatures above 180 K in our devices, the variation at lower temperatures is contrary to expectations. To understand this variation, we first look into the temperature dependence of $R_{sq}$ of graphene (Figure 3d). We note that the spin transport parameters are unchanged in the temperature regime 4–180 K, where the variation of $R_{sq}$ is the largest. This is clearer if we analyze the carrier density using Einstein relation $n = \frac{(h\nu_F)^2 \pi}{g_s\epsilon_F D_s R_{sq} e^2}$, assuming $D_s \approx D_i$:

$$n = \frac{(h\nu_F)^2 \pi}{g_s\epsilon_F D_i R_{sq} e^2}$$  \hspace{1cm} (1)

where $R_{sq}$ is the square resistance of graphene, $\nu_F$ is the Fermi velocity, $h$ is the reduced Planck’s constant, $g_s = 2$, $g_\epsilon = 2$ are the spin and valley degeneracy respectively, $D_s$ is the charge
contact resistance (depending on the ratio between the resistance of the contacts), the resistive channel can be backscattered into the electrodes. Spins from the low resistive ferromagnetic contacts to the high resistive graphene interface all play a cumulative role in the observed uncertainty in the determination of the carrier density and contact resistance with temperature. Inferred that the invasiveness of the contacts do not play a crucial role in the observed temperature variation of the spin transport parameters.

We now consider the role of spin-orbit coupling in STO to explain the reduction in spin relaxation times at low temperatures. An electric field induced (via spin orbit coupling) change in the spin relaxation time has been demonstrated earlier in graphene and also in doped-STO.[20] In our case, the origin of the electric field is intrinsic to the STO substrate. The surface of STO has a broken inversion symmetry and is found to harbor surface dipoles where the oxygen atoms are displaced outward.[25,35] The strength of these surface dipole moments is calculated to be $P = -13.89 \mu \text{Ccm}^{-2}$ which increases to $P = -34.90 \mu \text{Ccm}^{-2}$ with the graphene layer.[18,36] This electric field, pointing outwards from the substrate plane, originates from the surface dipoles in STO. The strength of this electric field is enhanced by the increased $\tau_s$ in STO at low temperatures. This intrinsic electric field effectively influences the spin relaxation time in graphene via spin-orbit coupling. With increasing temperature, a reduction in the surface electric field occurs due to the slowly relaxing surface dipoles,[25] leading to an increase in the spin relaxation time. At temperatures above 180 K, the electron phonon scattering plays an important role, leading to a slight decrease of $\tau_s$, $D_s$, and $\lambda_s$.

Further, structural transition in STO at 105 K, that leads to the formation of long striped domains and induces ripples on the graphene surface, are important considerations in the analysis of the temperature dependence of transport in graphene. Recent studies show that below the cubic to tetragonal phase transition temperature of 105 K, differently oriented large (micron size) tetragonal domains are formed in STO where the local electrostatics are different than at the domain walls.[20,21] These will induce surface potential modulations across the graphene sheet (see the charge transport data in Figure S2, Supporting Information) on STO and will vary strongly with temperature. The induced ripples will act as local scattering centers at low temperatures leading to enhanced spin dephasing and hindering efficient spin transport.

From our detailed analysis above, we infer that the variation of the carrier density and contact resistance with temperature can be eliminated as factors influencing the temperature dependence of the spin transport in graphene. However, as discussed above, mechanisms such as electric field induced by the surface dipoles, intrinsic spin orbit coupling and potential modulations due to temperature induced rippling at the graphene interface all play a cumulative role in the observed spin relaxation times at low temperatures. This intrinsic electric field effectively influences the spin relaxation time in graphene via spin-orbit coupling. With increasing temperature, a reduction in the surface electric field occurs due to the slowly relaxing surface dipoles,[25] leading to an increase in the spin relaxation time. At temperatures above 180 K, the electron phonon scattering plays an important role, leading to a slight decrease of $\tau_s$, $D_s$, and $\lambda_s$.

Further, structural transition in STO at 105 K, that leads to the formation of long striped domains and induces ripples on the graphene surface, are important considerations in the analysis of the temperature dependence of transport in graphene. Recent studies show that below the cubic to tetragonal phase transition temperature of 105 K, differently oriented large (micron size) tetragonal domains are formed in STO where the local electrostatics are different than at the domain walls.[20,21] These will induce surface potential modulations across the graphene sheet (see the charge transport data in Figure S2, Supporting Information) on STO and will vary strongly with temperature. The induced ripples will act as local scattering centers at low temperatures leading to enhanced spin dephasing and hindering efficient spin transport.

non monotonous temperature variation of the spin transport parameters. Using STO as a back gate, we can tune the surface dipoles on the surface of STO at 4 K as shown in Figure 4. \( e_r \) of STO increases from 300 at room temperature to more than 24,000 at 4 K. A back gate modulation of the surface dipoles through a 0.5 mm thick STO substrate is realized at 4 K. Beyond 4 K, the decreased \( e_r \) render the back gating less efficient, making it difficult to draw any reasonable conclusions on the gate dependence of spin relaxation at higher temperatures. We have swept the back gate between 70 and \(-70\) V and wait for 600 s before the start of each spin transport measurement. As shown in Figure 4e and f, the intrinsic surface dipole strength will be enhanced at negative gate voltage and reduced at positive gate voltage, thus influencing the spin relaxation time. We observe that \( \tau_s \), \( D_s \), and \( \lambda_s \) increases up to a factor of two at higher positive \( V_g \), while at negative and small positive gate voltage, these parameters do not seem to change much, as shown in Figures 4a–c.

There are two prevalent spin relaxation mechanisms in graphene. The first is the Elliot–Yafet (EY) mechanism, where the spin loses its direction by scattering with the impurities and the spin-relaxation time is inversely proportional to the momentum relaxation time. The second mechanism is the D’yakonov–Perel’ (DP) mechanism, where the spin precesses in a spin-orbit field between two momentum scattering events and the spin relaxation time is inversely proportional to the momentum relaxation time. To further quantify the relative contribution of the Elliot–Yafet (EY) and D’yakonov–Perel’ (DP) mechanisms in our case, we assume \( D_s \approx D_i \) and calculate the momentum relaxation time \( \tau_p \) according to \( D_s \sim v_F^2 \tau_p \). Following the standard analysis as used by Zomer et al., Jo et al., and Gurram et al.,\(^{[7,8,37]}\) we analyze the relation between \( \tau_p \) and \( \tau_s \) using the equation:

\[
\frac{E_F^2 \tau_p}{\tau_s} = \Delta_{EY}^2 + \left( \frac{4 \Delta_{EY}^2}{\hbar^2} \right) E_F^2 \tau_p
\]  

(2)

where \( E_F \) is the Fermi energy, \( \Delta_{EY} \) and \( \Delta_{DP} \) are the spin orbit coupling for EY and DP mechanism, respectively. Figure 4d shows the \( \tau_s^2 \) versus \( E_F^2 \tau_p^2 \) dependence. From the fitting, we extract \( \Delta_{EY} = 532 \mu \text{eV} \) and \( \Delta_{DP} = 147 \mu \text{eV} \).

We further consider the variation of \( e_r \) by an applied gate bias and analyze the spin relaxation mechanism in graphene. \( e_r \) of STO can be calculated using\(^{[38,39]}\)

\[
e_r(T, E) = \frac{b(T)}{\sqrt{a(T) + E^2}}
\]  

(3)

where \( T \) is the temperature, \( E \) is the electric field, fitting parameters \( b(T) = 1.37 \times 10^7 + 4.29 \times 10^6 (\text{V/cm}) \) and \( a(T) = b(T)/\omega_f (T, 0)^2 \text{V}^2/\text{cm}^2 \), and \( e_r(T, 0) \) is expressed using Barrett’s formula\(^{[40]}\)

\[
e_r(T, 0) = \frac{1635}{\coth(44.1/T) - 0.937}
\]  

(4)

The calculated variation of \( e_r \) on back gate is shown in Figure 5a. We incorporate the variation of \( e_r \) in our calculation of \( E_F \) using \( n = 4 E_F^2 / (g_F e h^2 v_F^2) = \frac{e_0}{\varepsilon_0} \Delta V_g \), where \( e_0 \) is the vacuum permittivity and \( t \) is the thickness of STO (0.5 mm). Figure 4d is now reanalyzed considering this variation of \( e_r \) by the applied electric field and this is shown in Figure 5b. From

![Figure 4. Gate dependent spin transport parameters at 4 K. a–c) Gate dependence of \( \tau_s \), \( D_s \), and \( \lambda_s \). The gate is swept between 70 V to \(-70\) V. Higher \( \tau_s \), \( D_s \), and \( \lambda_s \) values are observed at positive positive gate voltage. Note: below \(-40\) V, the Hanle curves cannot be fitted with the steady state solution to the one-dimensional Bloch equation. d) \( \frac{E_F^2 \tau_p^2}{\tau_s^2} \) versus \( E_F^2 \tau_p^2 \) at 4 K. The solid line is the fit using Equation (2). The error bars are the fitting errors. e,f) Surface dipoles at \( V_g > 0 \) and \( V_g < 0 \). At positive gate voltage, the surface dipoles are suppressed by the electric field; at negative gate voltage, the surface dipoles are enhanced.](Image)
Figure 5. a) Gate dependent $\varepsilon_i$ at 4 K calculated using Equation (3). b) $\varepsilon_i^{-1} \tau_{\varepsilon_i}$ versus $E^2 \tau_p^2$ at 4 K taking into account the variation of $\varepsilon_i$ with gate bias. The calculated data points incorporating the dielectric constant correction are represented by the stars, and the blue solid line is the fit using Equation (2). The error bars are the fitting errors.

Figure 5b, we obtain $\Delta_{\text{EY}} = 537 \mu$eV and $\Delta_{\text{DP}} = 162 \mu$eV (the respective numbers in Figure 4d are $\Delta_{\text{EY}} = 532 \mu$eV and $\Delta_{\text{DP}} = 147 \mu$eV). Reported values of spin relaxation mechanisms in graphene on hBN and on other substrates\textsuperscript{[7,8,37]} shows $\Delta_{\text{DP}}$ to be varying between 40–200 $\mu$eV and $\Delta_{\text{EY}}$ between 0.5 and 2.3 meV with no clear dominance of either mechanism. The values we obtain from our fittings are similar to these values. Spin relaxation rates are further analyzed: $\tau_{\text{EY}} = 0.2 - 5.6 \text{ns}^{-1}$ and $\tau_{\text{DP}} = 0.02 - 0.09 \text{ns}^{-1}$, and are found to be of the same order for EY and DP spin relaxation mechanisms. We conclude that for graphene on STO, there is a coexistence of both mechanisms with no clear dominance of one mechanism over the other as reported for other substrates\textsuperscript{[7,8,37]}

In conclusion, we report on the first observation of spin transport in graphene on TiO$_2$-terminated STO with broken inversion symmetry. A spin relaxation time and length of 0.96 $\pm$ 0.03 ns and 4.1 $\pm$ 0.1 $\mu$m are obtained at 290 K along with a non monotonic variation of the spin transport parameters at low temperatures. Our work shows that spin transport in graphene on STO is influenced by the cumulative effect of surface electric dipoles, intrinsic spin–orbit coupling and temperature induced rippling of the graphene interface. Gate dependence of the spin relaxation parameters at 4 K is attributed to the modulation of the strength of the surface dipoles in STO, while an analysis of the spin relaxation mechanism shows the coexistence of both EY and DP scattering processes. Our studies on integrating graphene with complex oxides opens new opportunities to study proximity induced functionalities at such interfaces, useful for future spintronics and optoelectronics applications.
