Inferring Diversification Rate Variation From Phylogenies With Fossils

JONATHAN S. MITCHELL, RANPAUL S. ETIENNE, AND DANIEL L. RABOSKY.

Abstract—Time-calibrated phylogenies of living species have been widely used to study the tempo and mode of species diversification. However, it is increasingly clear that inferences about species diversification—extinction rates in particular—can be unreliable in the absence of paleontological data. We introduce a general framework based on the fossilized birth-death process for studying speciation–extinction dynamics on phylogenies of extant and extinct species. The model assumes that phylogenies can be modeled as a mixture of distinct evolutionary rate regimes and that a hierarchical Poisson process governs the number of such rate regimes across a tree. We implemented the model in BAMM, a computational framework that uses reversible jump Markov chain Monte Carlo to simulate a posterior distribution of macroevolutionary rate regimes conditional on the branching times and topology of a phylogeny. The implementation, we describe can be applied to paleontological phylogenies, neontological phylogenies, and to phylogenies that include both extant and extinct taxa. We evaluate performance of the model on data sets simulated under a range of diversification scenarios. We find that speciation rates are reliably inferred in the absence of paleontological data. However, the inclusion of fossil observations substantially improves the accuracy of extinction rate estimates. We demonstrate that inferences are relatively robust to at least some violations of model assumptions, including heterogeneity in preservation rates and misspecification of the number of occurrences in paleontological data sets. [BAMM; comparative methods; extinction; fossils; macroevolution; speciation.]

Variation in rates of speciation and extinction contributes to striking disparities in species richness among different clades of organisms. The study of macroevolutionary rates was pioneered in the fossil record, with the application of phenomenological birth–death models to patterns of diversity through time (Raup et al. 1973; Sepkoski 1978; Raup 1985). Phylogenies of extant species are widely used to estimate rates of both speciation and extinction (Nee et al. 1994; Nee 2006; Altay et al. 2009; Morlon 2014). However, the integration of paleontological and neontological data will likely provide more accurate insights into macroevolutionary dynamics than molecular phylogenies alone (Quental and Marshall 2010; Liow et al. 2010a; Stadler 2013; Rabosky 2016). Indeed, a recent simulation study has argued that macroevolutionary rates inferred using only a tree topology and fossil occurrence dates are more reliable than rates inferred with an extant-only tree and branch lengths (Dierk et al. 2017).

Inferences on macroevolutionary patterns frequently differ between paleontological and molecular phylogenetic data (Hunt and Slater 2016). Fossil data routinely support high levels of extinction and large fluctuations in standing richness (e.g., Alroy 1999, 2008, 2010; Liow et al. 2010a; Quental and Marshall 2010; Sheets et al. 2016). However, extant-only analyses rarely find support for high extinction rates (Nee 2006; Purvis 2008, but see Etienne et al. 2012), and numerous studies have addressed potential reasons for this discrepancy (Rabosky 2009, 2010, 2016; Morlon et al. 2011; Etienne and Rosindell 2012; Etienne et al. 2012; Rosenblum et al. 2012; Beaulieu and O’Meara 2015). Directly incorporating fossil data into phylogenetic rate estimation should facilitate more robust tests of the role of extinction in macroevolutionary dynamics (Sakamoto et al. 2016). An explicitly phylogenetic approach to macroevolutionary rates in the fossil record will provide insights into rate variation among lineages and will also facilitate the study of diversification dynamics in clades that are too poorly preserved for subsampling-based approaches (e.g., Alroy 1999).

In this article, we describe a general framework for modeling complex speciation–extinction dynamics on phylogenetic trees that include both paleontological and neontological data. The model is based on the fossilized birth–death process (Stadler 2010; Didier et al. 2012, 2017; Heath et al. 2014) and includes parameters for speciation, extinction, and fossilization rates. The birth–death process for reconstructed phylogenetic trees (Nee et al. 1994) is a special case of the fossilized birth–death process where the preservation rate is equal to zero (Stadler 2010). Such, this model can be applied to paleontological phylogenies (extinct taxa only), neontological phylogenies of living species (extant taxa only), and phylogenies that include any combination of extant and extinct species.

The novel feature of our implementation, relative to previous work on diversification rates from phylogenies and fossils (Stadler 2010; Didier et al. 2012; Heath et al. 2014), is the ability to capture complex patterns of among-lineage variation in speciation and extinction rates. The model assumes that phylogenies are shaped by a countably finite set of distinct evolutionary rate regimes, and that the number of such regimes
is governed by a hierarchical Poisson process. This model is an extension of the multiprocess diversification model currently implemented in the BAMM software package for macroevolutionary rate analysis (Rabosky 2014; Rabosky et al. 2017). We note that Sakamoto et al. (2016) developed a flexible regression-based framework for estimating heterogeneity in diversification rates from fossil phylogenies, but their approach does not rely on a formal process-based model of diversification and preservation.

We first describe the analytical formulation of the model and state its assumptions. We then describe our implementation within the BAMM software framework and discuss its relationship to previous BAMM versions (Rabosky et al. 2017). To evaluate the performance of the model, we simulated phylogenies under a range of diversification scenarios, and then subjected each simulated phylogeny to stochastic fossilization to generate a tree similar to what researchers would typically use (an “observed” phylogenetic tree with an incompletely fossilized history). We analyzed each phylogeny with BAMM and compared the BAMM-inferred rates and shift configurations to the known (simulated) values to assess the accuracy of parameter estimates. We find that the inclusion of even sparse paleontological data in phylogenies dominated by extant lineages improves the accuracy of both speciation and extinction rate estimates. This improvement is especially pronounced in phylogenies dominated by extant lineages. Although our model makes several simplifying assumptions about the nature of fossilization, we demonstrate that rate inferences are reasonably robust to temporally-heterogeneity in preservation rates.

**METHODS**

**Data**

The data consist of a time-calibrated phylogenetic tree (which may include both extinct and extant lineages) and a count of the number of stratigraphically-distinct fossil occurrences associated with the tree. Each extinct lineage in the phylogeny should be represented by a branch that terminates at the time of the last occurrence for the taxon. The number of fossil occurrences is best thought of as an estimate of the true extinction time of a taxon. The number of fossil occurrences associated with the tree is expected to precede the last occurrence time for the taxon. In the phylogeny should be represented by a branch that terminates at the time of the last occurrence for the taxon. Note that true extinction events are not observed directly, and the last occurrence time is expected to precede the true extinction time of a taxon. The number of fossil occurrences is best thought of as an estimate of the number of fossils that could be, in principle, assigned to lineages present in the tree. Fossil occurrences of lineages not present in the tree (e.g., “Theropoda, indeterminate”) are not accommodated in this modeling framework and are excluded from the count of occurrences; the likelihood calculations only apply to fossils that can be assigned explicitly to branches in the tree. Put another way, fossil occurrences should only be counted if the species-level taxon to which they are assigned is included in the tree. However, because the current implementation assumes homogeneity of preservation through time and among lineages, the calculations do not actually use stratigraphic and phylogenetic context for individual fossil observations. As explained below, this assumption of time-homogeneous preservation means that the likelihood of the phylogeny with fossil data is invariant with respect to the location of the fossils on the tree.

**Likelihood of a Phylogeny with Fossils and Rate-Shifts**

The fundamental operation in the analysis of diversification rate shifts on phylogenetic trees involves computing the likelihood of the phylogeny under a fixed configuration of lineage types. Each “type” of lineage is characterized by a distinct and potentially time-varying rate of speciation ($\lambda_i$) and extinction ($\mu_i$). Two lineages $i$ and $j$ are said to be of the same type if $\lambda_i(\Delta t) = \lambda_j(\Delta t)$ and $\mu_i(\Delta t) = \mu_j(\Delta t)$ everywhere in time. Thus, for a given point in time $t$, lineages of the same type will have precisely the same distribution of progeny lineages at some time $t + \Delta t$ in the future. For the constant-rate birth–death process, all lineages are assumed to be of the same type. For the Binary State Speciation and Extinction (BiSSE) process (Maddison et al. 2007), phylogenies are assumed to comprise a mixture of two types of lineages, and the character states at the tips of the tree can be viewed as labels for lineage types. The transition points between types are unknown in the BiSSE process, and the likelihood of a given set of labeled types can be computed by integrating over all possible transitions that could have given rise to the observed data.

In contrast to BiSSE, the calculations implemented in BAMM and other rate-shift models (Alfaro et al. 2009; Morlon et al. 2011; Etienne and Haegeman 2012) assume that we have mapped lineage types across all branches of the phylogeny and not merely to the tips. We define a “mapping” of rate parameters as an association between each point on a phylogeny (e.g., segment of a branch) and a particular lineage type. Additional steps may be used to optimize the number, location, and parameters of the mapped types, including maximum likelihood (Alfaro et al. 2009; Morlon et al. 2011; Etienne and Haegeman 2012).

Likelihood calculations for the fossilized birth–death process were described by Stadler (2010), and our general approach extends these calculations to a phylogeny with multiple types of lineages. The fossilized process differs from the reconstructed evolutionary process (Nee et al. 1994) because we must also account for the lineage fossilization rate $\psi$. The new calculations described below are implemented in BAMM v2.6.

The derivation of the likelihood for rate-shift models follows the logic described in Maddison et al.’s (2007) description of the BiSSE model. In a given infinitesimal interval of time $\Delta t$, the state-space for the process includes five events that can potentially change the probability of the data: a lineage may undergo a rate shift, become preserved as fossil, become extinct, speciate, or it may undergo none of these events. To compute the likelihood of the tree and a set of parameters
(e.g., a mapping of rate shifts), we assume that no other rate shifts have occurred, thus dropping one of the possible events (the occurrence of an unmapped rate shift) from the state space for the process. As such, the likelihood is conditioned on the set of shifts that have been placed on the tree. This assumption of rate-shift models has been criticized in the recent literature (Moore et al. 2016). However, it is unclear how we might accommodate unobserved rate shifts, even in principle, as there is very little information in the data or elsewhere that can yield information about the probability distribution of unobserved rate parameters. Most importantly, we demonstrate that the simplifying assumptions that underlie the BAMM calculations yield robust inference on evolutionary rates, even when simulated phylogenies used for validation contain many such unobserved rate shifts.

We assume that preservation events are mutually exclusive with respect to speciation and extinction events. Hence, a lineage cannot leave a recoverable fossil observation during the precise moment of lineage splitting or lineage extinction. This interpretation of the preservation rate ensures that the model we have implemented is mathematically identical to the model described by Stadler (2010), for the special case where speciation and extinction rates do not vary among lineages. This interpretation of preservation is also consistent with paleontological practice: fossil observations are always assigned to single lineages. Even in the relatively high-resolution marine microfossil record, paleontologists do not assume that the data capture the precise instant of lineage splitting (Benton and Pearson 2001). In this article, we assume that lineage preservation is a time-homogeneous process, but it is straightforward to relax this assumption.

We measure time $t$ backwards from some arbitrary starting time, $t_0$. The start time, $t_0$, need not correspond to the present. Let $D(t)$ be the probability density that a lineage that is extant some time $t$ before $t_0$ gives rise to the observed data at the present time, and let $E(t)$ be the corresponding probability that a lineage that is extant at time $t$ goes extinct, along with its descendants, before time $t_0$. Following Stadler (2010), the master equations governing the likelihood of the data are

$$\frac{dD}{dt} = -(\lambda + \mu + \psi)D(t) + 2\lambda D(t)E(t)$$

(1)

and

$$\frac{dE}{dt} = -(\lambda + \mu + \psi)E(t) + \lambda E(t)^2$$

(2)

$E(t)$ describes the probability that an independent lineage originating at time $t$ goes extinct, along with all of its descendants, before some future time $t_0$. One can also view this probability as the probability of "non-observation" of a lineage and all of its descendants; a lineage and its descendants might not be observed because they have gone extinct, and/or because we have failed to sample them. To compute the likelihood of the phylogeny with mapped rate shifts, we require solutions to these equations for arbitrary $t$ and initial values $l_0$, $D_0$, and $E_0$. For $E(t)$, the solution is (Stadler 2010)

$$E(t) = \frac{\lambda + \mu + \psi + c_1 e^{-c_2(t-t_0)} - (1+c_2)}{2\lambda}$$

(3)

where

$$c_1 = \sqrt{(\lambda - \mu - \psi)^2 + 4\lambda \psi}$$

(4)

and

$$c_2 = \frac{\lambda - \mu - \psi - 2\lambda (1-E_0)}{c_1}$$

(5)

For $D(t)$, we have

$$D(t) = \frac{4D_0}{2(1-c_2) + e^{-c_1 t}(1-c_2)^2 + e^{-2c_1 t}(1+c_2)^2}$$

(6)

which follows immediately from Stadler (2010) Theorem 3.1, under the substitution $D_0 = \rho$. In the Supplementary Material, we provide a derivation of $D(t)$ for arbitrary $D_0$.

Calculations are performed by solving $D(t)$ and $E(t)$ recursively on the phylogeny from the tips to the root, combining $D(t)$ probabilities at internal nodes (discussed below) and continuing down the tree in a rootwards direction. For lineages that are extant, we have initial conditions at time $t_0 = 0$ of $D_0 = \rho$ and $E_0 = 1 - \rho$, where $\rho$ is the probability that an extant lineage has been sampled (e.g., the sampling fraction; FitzJohn et al. 2009). In the absence of perfect preservation, the last fossil occurrence of a given taxon is not the true extinction time. For a lineage with a last occurrence at time $t_i$, we generally know that the lineage and all of its descendants went extinct sometime between $t_i$ and $t_0 = 0$. Hence, for terminal lineages with non-extant tips, we initialize both $D_0$ and $D_0$ with $E(t, t_0 = 0)$, or the probability that a single lineage that is extant at time $t_i$ will have zero observed descendants prior to and including the present day ($t = 0$). This initialization for $D_0$ accounts for the probability that a non-extant tip goes extinct, or is unsampled, on the time interval ($t_i$, 0). At internal nodes, we combine the densities from the right $D_0(t)$ and left $D_0(t)$ descendant lineages, such that $D(t)$ immediately rootwards of the node is computed as $D(t) = \lambda(t)D_0(t)D_0(t)$. The full likelihood must also account for all $Z$ observed fossil occurrences, which is accomplished by multiplying the probability density of the tree by $\Psi^Z$. There is one difference between the implementation of the model described here (implemented in BAMM v2.6) and the default calculation scheme implemented in the most recent previous version, BAMM v2.5. As discussed in Rabosky et al. (2017), there are several algorithms for computing the likelihood of a specified mapping of rate regimes on a phylogenetic tree. These algorithms, which we have termed "recompute" and "pass-up" (Rabosky et al. 2017), differ in how the analytical $E(t)$ equation is initialized for calculations on
individual branch segments. The precise sequence of calculations associated with these approaches is described in the Supporting Information (Section S2.4 available on Dryad at https://doi.org/10.5061/dryad.5om70) from Rabosky et al. (2017). Herein, we expand BAMM to include the “recompute” algorithm for computing the likelihood, which was not implemented as the default calculation scheme in BAMM v2.5. The process under consideration in the present article can yield phylogenies that have gone extinct in their entirety (e.g., fossil taxa only), and we can thus avoid conditioning on survival of the process as well as unresolved theoretical problems associated with this conditioning. We thus perform all calculations using both the “recompute” and “pass-up” algorithms; we present “recompute” results in the main text, but the corresponding results using “pass-up” were virtually identical and are presented in the Supplementary Information available on Dryad.

As noted above, our use of these equations for modeling diversification dynamics implicitly conditions the likelihood on a finite and observed set of lineage types: the likelihood does not account for new types of lineages that may have evolved on lineages with no fossilized or extant descendants (Moore et al. 2016). This assumption applies to all methods that purport to compute the likelihood of a phylogeny under a specified mapping of rate shifts (Alfaro et al. 2009, Morlon et al. 2011, FitzJohn 2010, Etienne and Haegeman 2012). Indeed, this assumption applies indirectly to all diversification methods: if there are no (or very few) unobserved shifts, the likelihood computed by BAMM is approximately correct. If “reality” contains many such unobserved shifts, then the likelihood (and corresponding rate estimates) from BAMM will be biased, because rate shifts will essentially have served as an unaccommodated source of lineage extinction. But if unobserved rate shifts are sufficiently common (in real data) as to bias BAMM, then they are problematic for all other current methods and models as well. As pointed out by Rabosky et al. (2017), the problem of unobserved rate shifts does not disappear simply because one assumes a theoretically complete model that ignores their existence or by sampling their parameters from a prior (assumed) distribution.

Implementation in BAMM

The model described above is implemented as an extension to the BAMM software (v2.6). BAMM v2.6 expands the basic diversification model implemented in earlier versions of BAMM by incorporating parameters that specify the total observation time of the tree (“observationTime”, \(T_{\text{obs}}\): time from root when the tree is observed; this parameter is equal to the root age for trees with extant lineages), the total number of observed fossil occurrences within the clade analyzed (“numberOccurrences”), and parameters that control the prior distribution of, and update frequency for, the preservation rate \(\Psi\) (“updatePreservationRate”, “preservationRatePrior”, and “preservationRateInit”). \(T_{\text{obs}}\) can have a large impact on the overall model fit, and warrants additional explanation. The model assumes that non-extant tip lineages can go extinct anywhere on the time interval that extends from their last occurrence to \(T_{\text{obs}}\). Consider the scenario where we are modeling diversification dynamics in an extinct clade of dinosaurs that originated 200 million years before the present (Ma) and where the last occurrence of that clade is 90 Ma. If we set \(T_{\text{obs}}\) to equal the present day (0 Ma), the model will allow the possibility that the last dinosaur from the clade went extinct sometime between 90 and 0 Ma. In practice, we suggest choosing the observationTime as the earliest possible time that all last-occurrence taxa are believed to have gone extinct. In the dinosaur example, a reasonable setting for \(T_{\text{obs}}\) would be the KPg boundary at 66 Ma, by which time all non-avian dinosaur lineages had become extinct.

The number of occurrences (parameter “numberOccurrences” in BAMM) represents the total number of fossil occurrences that can be assigned to observed lineages in the clade under consideration and is not simply the number of extinct tips in the phylogeny. It is necessarily the case that a phylogeny with \(k\) extinct tips has at least \(k\) occurrences for the last occurrence of each extinct lineage; however, there can be multiple occurrences for each extinct and extant lineage. There are several possible interpretations of a fossil occurrence in the BAMM framework; we address this issue at length in the Discussion section. Occurrences associated with fossil taxa that are not present in the tree should not be used, nor should taxonomically indeterminate material (e.g., fragmentary fossil material that cannot be taxonomically identified below the genus level). In general, we consider an “occurrence” to represent stratigraphically-unique species-level observations. Hence, a locality with 1000 individuals of a single taxon representing a single depositional event (e.g., a mass burial event) would constitute a single occurrence. In practice, we suggest analyzing a data set with several different values for the occurrence count to ensure that results are robust (see Discussion section).

Description of Tree Simulation

We developed software to simulate phylogenies under a Poisson process that includes shifts to new macroevolutionary rate regimes (https://github.com/macroevolution/simtree). Each simulation was initialized with two lineages at time \(t = 0\) with \(\lambda\) and \(\mu\) drawn from exponential distributions with means of 0.2 and 0.18, respectively. We assumed that shifts to new rate regimes occurred with rate \(\Lambda = 0.02\). Waiting times between events (speciation, extinction, rate shift) were drawn from an exponential distribution with a rate equal to the sum of the rate parameters \((\lambda + \mu + \Lambda)\). For rate shift events, new values of \(\lambda\) and \(\mu\) were drawn from the same exponential distributions as the root regime. This procedure simulates a phylogeny with stochastic rate shifts; within a given rate regime, \(\lambda\) and \(\mu\) were constrained to be constant in time.
Simulations were run for 100 time units, and trees with more than 5000 or fewer than 50 lineages at \( t = 100 \) were discarded, resulting in a total of 200 trees for analysis. In addition, each tree was constrained to have at least one rate shift in the true, generating history. This simulation procedure can generate phylogenies with unobserved rate shifts when shifts occur in unsampled extinct clades (see below). Conversely, the true root regime may be unobserved and all observed tips may fall within one of the derived regimes. As discussed in the section below on fossilization, any rate shift that leads to an extinct clade with no fossil observations will be unobserved, thus enabling us to assess whether Moore et al.’s (2016) concerns about unobserved rate shifts have consequences for inference in practice.

**Description of Fossilization Procedure**

We created pseudo-fossilized trees by stochastically placing fossils along the branches of each simulated tree (Fig. 1) using per-lineage preservation rates \( \psi \) of 0, 0.01, 0.1, or 1.0. Speciation rates in our simulations ranged from 0.003 to 1.7 lineages per unit time, with 99% of the regimes having a speciation rate above 0.015; 80% exceeded 0.1. As such, speciation events were generally more frequent than fossilization events, except under the high preservation \( \psi = 1.0 \) simulation scenario. All extant tips, and tips with at least one fossil occurrence, were retained while tips (and clades) lacking fossil occurrences were dropped. In empirical data sets, the true extinction time of an extinct lineage is unknown, and the time of the last (most recent) fossil occurrence is used. For comparability with empirical data from the fossil record, extinct tips with fossils were truncated to the time of the most recent fossil occurrence (e.g., the branch ends at the last occurrence, and any subsequent history for the lineage is necessarily unobserved). We refer to these pseudo-fossilized trees as “degraded,” because the stochastic fossilization history necessarily discards information about the true lineage history.

As pointed out by Moore et al. (2016), the model implemented in BAMM assumes that rate shifts do not occur on unobserved branches. However, our simulation and fossilization procedure allows rate shifts to occur on extinct clades with no fossil observations. Hence, our fossilization procedure frequently leads to unobserved rate regimes and enables us to test the practical significance of this core BAMM assumption.

**BAMM Analyses**

We approximated the posterior distribution of rate shift configurations for each degraded tree by running a Markov chain Monte Carlo (MCMC) simulation in BAMM v2.6 for 50 million generations, with the first 5 million discarded as burnin. Each tree was analyzed assuming a single, time-constant rate of preservation. The model prior (mean of the geometric prior distribution on the number of shifts) was set to 200 for all runs (after Mitchell and Rabosky 2016), while the rates of the exponential priors on \( \lambda \) and \( \mu \) were scaled using the setBAMMPriors() function in BAMMTools (see Supplementary Material available on Dryad for details). Mitchell and Rabosky (2016) found that inferences on the number of shifts were generally robust to the choice of model prior, but that use of a liberal model prior facilitated convergence of the MCMC simulation. We performed each analysis using both “recompute” and “pass-up” algorithms for computing the likelihood, as described by Rabosky et al. (2017). All computer code, data files, and result files are available through the Dryad digital data repository (https://doi.org/10.5061/dryad.50m70).

**Performance Assessment**

To assess the performance of our model and BAMM implementation, we quantified four fundamental attributes of interest: 1) the estimated preservation rate, 2) the speciation and extinction estimates inferred for each (true) rate regime, 3) the inferred number of macroevolutionary regimes on the tree, and 4) the location of inferred rate shifts. We compared the posterior distribution of the estimated preservation rate \( \psi \) for each degraded
tree to the generating value. For diversification rates we found the mean inferred speciation and extinction rates for every true regime with at least two tips (both extinct and extant), and compared these mean values to the true values of speciation (\( \lambda \)), extinction (\( \mu \)) and relative extinction (\( \mu / \lambda \)). We predicted that BAMM would estimate rates more accurately for regimes with larger numbers of taxa; we thus assessed BAMM's accuracy with explicit reference to the number of tips in each regime. This allowed us to assess how well BAMM estimates rates for regimes that differ in size.

We determined the best-supported number of shifts for each tree by using stepwise model selection with Bayes factors (Mitchell and Rabosky 2016). Using the posterior distribution of shifts for each tree, we compared the lowest complexity model (e.g., smallest number of shifts) to the next-most complex model. If the more complex model was supported by Bayes factor evidence of at least 20 relative to the simpler one, it was provisionally accepted and the process repeated with models of increasing complexity until the Bayes factor threshold of 20 was no longer exceeded. We then compared the best-supported number of shifts on the tree to the true number of preserved shifts (see Fig. 1).

Finally, we looked at how accurately BAMM inferred the locations of shifts along the tree. Location accuracy is difficult to quantify, as many simple metrics have undesirable properties. For example, the distance along the branches between a true and inferred shift is difficult to interpret unless the number of inferred shifts is exactly equal to the number of true shifts. Branch lengths further confound location accuracy as shifts along shorter branches are expected to be more “smeared” across adjacent branches relative to shifts on longer branches (see extensive discussion of this topic in the supplement to Mitchell and Rabosky 2016). We thus assessed location accuracy using several complementary metrics.

The first metric we used for location accuracy was the marginal posterior probability of at least one rate shift on all branches that included a (true) rate shift. We assessed these marginal probabilities with respect to both the magnitude of the shift (e.g., size of the rate increase) as well as the number of tips descending from that shift, with the expectation that shifts with many descendant tips and/or with a large change in rates would have higher marginal posterior probabilities. As pointed out by Rabosky (2014), focusing on these marginal probabilities can be misleading if the evidence for a rate shift is “smeared” across a set of adjacent branches.

As an alternative metric of location accuracy, we used the method described by Mitchell and Rabosky (2016) to assess how well BAMM partitions tips into their correct rate classes. This approach can be motivated by noting that any placement of \( k \) rate shifts on a phylogeny partitions a tree into at most \( k+1 \) subsets of tips with distinct rate regimes (\( k+1 \), not simply \( k \), due to the presence of a root regime that is distinct from the rate shifts). For a phylogeny with \( N \) taxa and a known (true) mapping of diversification regimes, there is an \( N \times N \) matrix where each element \( C_{i,k} \) describes whether the \( i \)th and \( k \)th taxa are assigned to the same or different rate regimes (the set of tips partitioned into a particular rate regime was termed a “macroevolutionary cohort” in Rabosky 2014). Elements of the matrix \( C_{i,k} \) take a value of 1 (if taxa \( i \) and \( k \) are in the same rate regime), or 0 (if \( i \) and \( k \) are in different rate regimes). Following BAMM analysis, we obtain a matrix \( D \) where \( D_{i,k} \) represents the posterior probability that taxa \( i \) and \( k \) are assigned to the same rate regime. To assess shift location accuracy, we computed one minus the average of the absolute value of the difference between the true pairwise partitioning matrix \( C \) and the BAMM-estimated matrix \( D \), or

\[
1 - \frac{2}{N(N-1)} \sum_{k=2}^{N} \sum_{i=1}^{k-1} |C_{i,k} - D_{i,k}|\n\]

An overall value of 1.0 can only be obtained if all pairs of taxa are correctly partitioned in the correct configuration of rate regimes in 100% of samples from the posterior. This metric of location accuracy will penalize shift configurations that include too many shifts (by separating taxa that should be in the same regime) and that include too few shifts (by uniting taxa that should be in separate regimes). However, the topology of the tree may make certain partitions more likely by chance alone. To quantify this baseline accuracy, we computed the partitioning accuracy that would be expected by chance if shifts were distributed randomly throughout the tree under a uniform prior with respect to the total tree length. Under a uniform prior, the probability of a shift on a given branch is simply \( b_i / T \), where \( b_i \) is the length of the \( i \)th branch and \( T \) is the tree length. We conditioned the randomization on the simulated shift count, such that each randomized sample contained exactly the same number of shifts as the corresponding sample from the posterior. After randomizing the placements of shifts from all samples in the posterior, we computed the accuracy of random partitions for each sampled generation using the same pairwise distance matrix approach described above.

\textit{Sensitivity of the Method to Model Violations}

We tested sensitivity of the framework described here to four qualitatively distinct violations of the assumptions of the underlying inference model. These violations included: 1) violation of time-homogeneous preservation potential; 2) misspecification of the true number of fossil occurrences in the data; 3) presence of a mass extinction in the data; and 4) diversity-dependent diversification. In real data sets, preservation rates can vary substantially even over relatively short timescales (Foote and Raup 1996; Holland 2016). We violated the assumption of time-constant preservation by applying a “stage-specific” preservation pattern to the simulated phylogenies. We use “stage” in this context solely to
denote an arbitrary temporal span with a potentially distinct preservation rate. We divided each simulated tree into ten equally-sized temporal bins (each ten time units long, mirroring the 10 myr bins used in some large-scale paleodiversity studies), where each bin was assigned an independent preservation rate drawn from a uniform (0.01, 0.9) distribution. We then simulated fossilization histories using these preservation rates and pruned unobserved lineage histories as described above to generate a set of degraded trees. We analyzed these trees using BAMM v2.6, which assumes time-homogeneous preservation, and we tested the accuracy of inference using the same metrics described above. Given that the simulated trees involve rate shifts, this simulation approach allows clades to radiate in periods of higher or lower preservation, and to persist into subsequent time bins with distinct and decoupled preservation parameters.

Our implementation assumes that users can specify a meaningful number of fossil occurrences for the clade. Fossil occurrences are not placed at specific points on the tree, but rather inform the model about the total number of fossil occurrences associated with the focal clade. The current implementation thus assumes fossil occurrences (with the exception of last occurrences) are distributed across the tree under a homogeneous Poisson process, and estimates a tree-wide rate accordingly. However, for real data sets, the “true” number of occurrences is likely imprecise (even in principle; see Discussion section). To assess how misspecification of the number of fossil occurrences may bias inference, we simulated 100 constant rate phylogenies, with higher rates than the variable-rate tree simulations (mean $\lambda = 0.9$, mean $\mu = 0.45$) and imposed a fossilization history with $\phi = 0.1$. Given the stochastic nature of the fossilization simulation, the fossilized trees varied in the number of extinct lineages observed. Note that because an extinct tip only is observed if at least one fossil occurs on that branch, each fossilized tree with (observed) extinct lineages has a minimum number of fossil occurrences equal to the number of (observed) extinct lineages.

We estimated the bias for each of these misspecified fossil occurrence values by dividing the inferred speciation and extinction rates across the entire tree (as inferred using the getCladeRates function from BAMMtools) by the true values used to simulate the tree. Our discussion below pertains to bias in rates resulting from misspecification of the number of occurrences, not bias due a particular magnitude of preservation (e.g., “low” or “high” preservation). We predict that overestimates of fossil occurrences should lead to underestimates of evolutionary rates. Essentially, as the number of fossil occurrences is increased, the inferred preservation rate will be higher; this increased preservation rate, in turn, will decrease the amount of unobserved evolutionary history that is assumed to have occurred. By reducing the inferred unobserved history through artificial inflation of the preservation rate, we underestimate the number of events that have occurred (speciation or extinction), and the corresponding rate estimates are biased downwards. When the observed number of fossil occurrences is lower than the true number, however, we will tend to overestimate both the unobserved evolutionary history and the corresponding diversification rates.

We also tested the impact of diversification histories that violate the assumptions of the BAMM framework using two scenarios. First, we asked how the recent extinction of a large clade may bias the estimates from BAMM. To simulate this scenario, we chose a single, large, extant clade on each simulated phylogeny and pruned each extant branch back to the time of the most recent fossil occurrence (or dropped it entirely, if it was never observed in the fossil record). For the 2nd scenario, we simulated trees under a diversity-dependent process, and inferred rates from that tree both with and without fossil data. Further details on these scenarios are presented in the Supplementary Materials (Section S8 available on Dryad).

### Empirical Analysis

For comparison purposes, we include an empirical analysis using BAMM of a recently published 138-tip phylogeny of horses (Cantalapiedra et al. 2017). We time-scaled the horse tree using the same approach as Cantalapiedra et al. (2017), which tends to homogenize branches by assuming all branch lengths are pulled from a single distribution defined by a speciation, extinction and preservation rate (see Bapt 2013; and the Supplementary Materials available on Dryad). We compared the BAMM results to those obtained using PyRate (Silvestro et al. 2014a,b), a Bayesian inference framework that allows estimation of diversification parameters and rate shifts from the occurrence data alone. We downloaded 1495 fossil occurrences (see Discussion) for the 138 species in the phylogeny from the Paleobiology Database (Alroy et al. 2001) using the R interface “paleoBioDB” (Varela et al. 2015). We simulated the posterior distribution of rate shift configurations using BAMM with 20,000,000 generations of MCMC sampling. The PyRate analysis used 1,000,000 generations of MCMC sampling.
RESULTS
Simulated trees varied from 50 to 4578 tips (mean = 770), and degrading the trees reduced the observed number of lineages to an average size of 589, 616, and 698 tips for the lowest to highest preservation rates. Because multiple fossilization histories were imposed on each fixed evolutionary history, the number of fossil occurrences scales directly with the preservation rate (mean numbers of fossils of 25.4, 255.6, and 2549.9 for the lowest to highest preservation rates). After 50 million generations, the MCMC chains for at least 95% of data sets in each fossilization scheme had reached our target convergence criterion, with effective sample sizes for the number of shifts at over 200. MCMC simulations that failed to meet this convergence criterion are nevertheless included in all following analyses to avoid biasing the sample by including only trees that showed good MCMC performance. Results based on all trees, even those that failed to achieve the desired effective sample sizes, are nearly identical to the results presented below and are shown in the Supplementary Material available on Dryad.

For each rate regime in each simulated tree, we compared the estimated rates with the true rates in the generating process. Estimated speciation rates were reasonably well correlated with true rates across all preservation levels. Across all rate regimes and preservation scenarios the correlation between true and estimated speciation rates was 0.49, although 70.9% of these regimes contained fewer than five tips. It is unlikely that BAMM would have had sufficient power to infer such small regimes (Rabosky et al. 2017), and we noted that BAMM-estimated rates perform well, despite the apparent conservatism of BAMM with respect to the number of shifts used in our analyses (Fig. 6). Using stepwise model selection with a Bayes factor threshold of 20, we identified spurious shifts in fewer than 0.5% of trees (Fig. 6). We tabulated the marginal posterior probability of a rate shift for each branch on which a (true) rate shift occurred. These marginal probabilities varied substantially but generally increased with the number of descendant tips across all preservation regimes (Fig. 7a).

As has been shown previously (Rabosky 2014), BAMM tends to be relatively conservative in the number of regimes on the tree even with the high prior on the number of shifts used in our analyses (Fig. 6). Using stepwise model selection with a Bayes factor threshold of 20, we identified spurious shifts in fewer than 0.5% of trees (Fig. 6). We tabulated the marginal posterior probability of a rate shift for each branch on which a (true) rate shift occurred. These marginal probabilities varied substantially but generally increased with the number of descendant tips across all preservation regimes (Fig. 7a). The marginal probability of a shift along a particular branch increases with both the magnitude of the rate increase and with the number of descendant lineages (Fig. 7b). Thus, BAMM substantially underestimates the number of rate shifts (Fig. 6), but shifts that are not detected tend to be those leading to small clades and/or those that represent small changes in evolutionary rates (Fig. 7). Tip partitioning accuracy in BAMM v2.6 was high overall, and did not vary systematically with preservation rate (Fig. 7c).

Because multiple fossilization histories were imposed on each fixed evolutionary history, the number of fossil occurrences scales directly with the preservation rate. Across all rate regimes and preservation rates, the mean correlation between true and estimated regime-specific rates was 0.14. As for speciation rates, correlations improve substantially when we exclude the 70.9% of rate regimes that included fewer than five tips. For regimes with five or more tips, correlations ranged from 0.30 for extant-only trees to 0.72 for the ψ = 1.0 scenario (Fig. 2). With 20 or more tips, these correlations increase to 0.49 and 0.91, respectively (Fig. 3). As with speciation, the slopes do not vary consistently with preservation, although the error decreases with increasing preservation rate (extant-only: slope all = 0.54 ± 0.02 and slope 20 = 1.20 ± 0.05 for all and regimes with 20+ tips; ψ = 0.01: slope all = 0.47 ± 0.02 and slope 20 = 0.95 ± 0.05; ψ = 0.1: slope all = 0.38 ± 0.01 and slope 20 = 0.78 ± 0.02; ψ = 1: slope all = 0.50 ± 0.01 and slope 20 = 0.95 ± 0.01).

The relative extinction rates (μ/λ), also improved with increasing preservation, with the estimates from extant-only simulations only weakly correlated with the true relative extinction level (r = 0.41 for 5+ tips, 0.53 for 20+ tips) and again increasing with increased preservation (r = 0.67 for regimes with 5+ tips; 0.87 for regimes with >20 tips; Figs. 2 and 3; right column). As for speciation, extinction rate correlations improve as we consider subsets of regimes with increasing numbers of tips, but accuracy of rate estimates is heavily influenced by the preservation rate (Fig. 4b). Preservation rates were estimated with high accuracy, with tight distributions around the generating values at ψ = 0.01, 0.1, and 1.0 (the 5 and 95% quantiles of the posterior estimate for ψ = 0.01 are 0.85 = 0.007 and 0.95 = 0.015; 0.95 = 0.09 and 0.95 = 0.12 for ψ = 0.1; 0.95 = 0.96 and 0.95 = 1.04 for ψ = 1; Fig. 5).

As has been shown previously (Rabosky et al. 2017), the BAMM estimator tends to be relatively conservative in the number of regimes on the tree even with the high prior on the number of shifts used in our analyses (Fig. 6). Using stepwise model selection with a Bayes factor threshold of 20, we identified spurious shifts in fewer than 0.5% of trees (Fig. 6). We tabulated the marginal posterior probability of a rate shift for each branch on which a (true) rate shift occurred. These marginal probabilities varied substantially but generally increased with the number of descendant tips across all preservation regimes (Fig. 7a). The marginal probability of a shift along a particular branch increases with both the magnitude of the rate increase and with the number of descendant lineages (Fig. 7b). Thus, BAMM substantially underestimates the number of rate shifts (Fig. 6), but shifts that are not detected tend to be those leading to small clades and/or those that represent small changes in evolutionary rates (Fig. 7). Tip partitioning accuracy in BAMM v2.6 was high overall, and did not vary systematically with preservation rate (Fig. 7c).
FIGURE 2. BAMM estimates of speciation (λ), extinction (μ), and relative extinction rate (μ/λ) estimates as a function of the true values for rate regimes with at least five tips from trees fossilized with different preservation rates. Each gray point is the estimated rate for a single rate regime. Black points represent mean estimated and inferred rates for all regimes falling within each 2% quantile of true rates. For example, the mean estimated rate of all individual regimes with a true rate between the lowest and the 2% quantile comprise the first black point. Rows give results for extant-only trees (1st row), low (σ = 0.01; 2nd row), moderate (σ = 0.1; 3rd row), and high (σ = 1.0; 4th row). Trees with higher preservation rates, and thus more fossils, have better rate estimates, with the extinction rate showing particular improvement.

massive underestimate of the number of shifts? The solution to this paradox lies in the fact that small rate shifts are missed by BAMM, but dominant rate classes across the tree are captured by BAMM with reasonable accuracy. Hence, BAMM might correctly infer only 3 of 15 rate regimes in a given phylogeny, but those three inferred regimes can govern the majority of branches in the tree (e.g., 12 shifts leading to one or two taxa, but the other three shifts all leading to 50 or more taxa).

Sensitivity of the Method to Model Violations

We found that the implementation performed well even when assumptions of homogeneous fossilization rates through time were violated. After imposing temporally-varying preservation rates on the data, we found that diversification rates were still estimated with high accuracy (Fig. 8). The estimates of both speciation and relative extinction (Fig. 8a,b) were reasonably correlated with the generating values. We also found very few
instances where the number of inferred shifts was higher than the generating model (Fig. 8c). Consistent with the time-homogenous preservation simulations, 78% of the tips were accurately partitioned among the rate regimes (Fig. 8d).

Underestimating the number of fossil occurrences inflates the speciation and extinction rates, while overestimating the number of occurrences deflates them (Fig. 9). Individual estimates of λ may be off by as much as 50% when misspecification is exceptionally high (Fig. 9a), while μ may vary by substantially more (Fig. 9b). However, in aggregate across all 100 trees, the median error at each level of occurrence misspecification is fairly low. Encouragingly, the correlations of tree-wide rate estimates for these constant rate trees are high even when the fossil occurrence numbers are off by a factor of ten (correlation for speciation: 0.95 to 0.89; correlation for extinction: 0.93 to 0.89). This suggests that, if the
distribution of mean. Black arrows denote the true value of \( \psi = 0.0032 \), while gray bars show the distribution of mean \( \psi \) across all 200 trees for each value.

We explored BAMM’s performance under two scenarios where the diversification process in the simulation model violated the assumptions of the inference model. For the diversity-dependent simulation model, we observed consistent biases in rate estimates when fossil and extant data were combined, and relative extinction rates were consistently biased upwards (Supplementary Fig. S10 available on Dryad). In contrast to the regime-specific assessments presented above, within-tree measures are difficult to interpret under rate-shift models like BAMM. If a method does not infer rate heterogeneity within the tree, the metrics (especially the slope) are expected to perform poorly. Rabosky et al. (2017) discusses this issue in detail, documenting how the metrics may be misleading even when rates on almost every branch are estimated with high accuracy. Regardless, there is no obvious trend between the proportion of unobserved shifts within a tree and the overall metrics of performance (Fig. 10).

Empirical Analysis

Our empirical analysis of the horse phylogeny yielded evidence for a major shift in rates leading up to the extant genus *Equus*, and also that speciation and extinction rates are approximately equal across the tree and through time (Fig. 11). Net diversification was found to be near-zero across the horse phylogeny (mean net div. = −0.002; of fossil information (Supplementary Fig. S11 available on Dryad); both speciation and extinction rates were estimated with much greater accuracy when fossils were included, relative to the extant-only analysis. For the mass extinction scenario, we observed consistent biases in rate estimates when fossil and extant data were combined, and relative extinction rates were consistently biased upwards (Supplementary Fig. S10 available on Dryad).

Unobserved shifts seem to have a negligible impact on rate estimation. Neither the slope nor correlation coefficient of the extinction and speciation rates for branches within trees varies with the proportion of unobserved rate shifts (Fig. 10), nor with the absolute number of unobserved shifts (see Supplementary Material available on Dryad). In contrast to the regime-specific assessments presented above, within-tree measures are difficult to interpret under rate-shift models like BAMM. If a method does not infer rate heterogeneity within the tree, the metrics (especially the slope) are expected to perform poorly. Rabosky et al. (2017) discusses this issue in detail, documenting how the metrics may be misleading even when rates on almost every branch are estimated with high accuracy. Regardless, there is no obvious trend between the proportion of unobserved shifts within a tree and the overall metrics of performance (Fig. 10).

Empirical Analysis

Our empirical analysis of the horse phylogeny yielded evidence for a major shift in rates leading up to the extant genus *Equus*, and also that speciation and extinction rates are approximately equal across the tree and through time (Fig. 11). Net diversification was found to be near-zero across the horse phylogeny (mean net div. = −0.002;
through time, but differs from the BAMM results in time if time-constancy of rates is assumed within rate duration of a particular rate regime. We caution users that temporal rate variation will be smeared across the 200 trees. The identity line is shown for reference, and the estimates slopes are very low (0.08, 0.085, and 0.18). The correlation between true and estimated numbers of shifts are 0.65, 0.73, and 0.8 for the preservations rates from lowest to highest. Plots in the top row show the results on the identical axes, while the plots in the 2nd row show the same data with the y-axis rescaled to better show the correlation between the true and estimated number of shifts. Most simulated shifts are small in terms of the number of lineages and they may also reflect a relatively minor change in rates (e.g., a shift from speciation of 0.1–0.11). As such, a method focused on summarizing the major regimes of the tree (i.e., those with strong support) is expected to underestimate the number of shifts. This is especially true when a stringent Bayes factor threshold is used (see SOM for the mean number of shifts from the posterior distribution).

Figure 6. The true number of shifts in the degraded trees plotted against the mean number of inferred shifts (number of non-root rate regimes best supported by stepwise model selection using Bayes factors) for preservation rates ($\psi$) of 0.01, 0.1, and 1.0. Each point represents one of the 200 trees. The identity line is shown for reference, and the estimates slopes are very low (0.08, 0.085, and 0.18). The correlation between true and estimated numbers of shifts are 0.65, 0.73, and 0.8 for the preservation rates from lowest to highest. Plots in the top row show the results on the identical axes, while the plots in the 2nd row show the same data with the y-axis rescaled to better show the correlation between the true and estimated number of shifts. Most simulated shifts are small in terms of the number of lineages and they may also reflect a relatively minor change in rates (e.g., a shift from speciation of 0.1–0.11). As such, a method focused on summarizing the major regimes of the tree (i.e., those with strong support) is expected to underestimate the number of shifts. This is especially true when a stringent Bayes factor threshold is used (see SOM for the mean number of shifts from the posterior distribution).

see Fig. 11), but lineage turnover rates were substantial (mean turnover = 0.7). This result is concordant with long-standing hypotheses about the history of life, where speciation is only slightly elevated relative to extinction, and only in some clades (e.g., Raup 1994). However, it is worth noting that the BAMM estimates assume that rates have been constant through time within rate regimes, and it is unlikely that this assumption is strictly true in practice. It is possible, for example, that the near-zero net diversification rates estimated for equids represent the long-term average of a clade that experienced a pronounced phase of positive net diversification followed by negative net diversification rates that led to extinction of many lineages (Quental and Marshall 2013; Cantalapiedra et al. 2017). BAMM’s assumption of time-homogeneous diversification means, in practice, that temporal rate variation will be smeared across the duration of a particular rate regime. We caution users of BAMM from overinterpreting rates at specific points in time if time-constancy of rates is assumed within rate regimes.

PyRate likewise infers an increase in extinction through time, but differs from the BAMM results in several ways. Extinction as estimated with PyRate was substantially lower than speciation during the earliest portion of horse evolution, but speciation dropped substantially at roughly 15 Ma and rebounded slightly at 6 Ma. The estimates of speciation and extinction from PyRate differ substantially from those estimated by BAMM, with greater volatility in the PyRate estimates of net diversification; BAMM inferred a more consistent near-zero level of net diversification. Notably, the turnover rates estimated by BAMM are much higher than those from PyRate. Both methods estimate high preservation rates, although as speciation, extinction, and preservation are estimated jointly, the two estimates are different, with BAMM estimating a higher rate ($\psi = 3.69 \pm 0.10$) than PyRate ($\psi = 2.27 \pm 0.07$).

Discussion

We have described an extension of the BAMM framework for modeling macroevolutionary dynamics that leverages recent advances in modeling the fossilized birth–death process (Stadler 2010; Ronquist et al. 2012; Heath et al. 2014; Didier et al. 2012, 2017) to estimate rates of speciation, extinction, and preservation from
shifts, because the evidence for a given shift can be smeared across several adjacent branches (Rabosky 2014). Red horizontal lines denote median inference model implemented in BAMM is robust to at phylogenies that include observations of fossil (non-extant) lineages. We found that BAMM was able to infer diversification rates, preservation rates, and the number and location of shift rates with reasonable accuracy across a range of fossilization scenarios. The inference model implemented in BAMM is robust to at least some violations of its assumptions, although we necessarily explored a limited subset of many possible ways that model assumptions can be violated. Given debates over the inference of extinction from molecular phylogenies (Rabosky 2010, 2016; Beaulieu and O’Meara 2015), it is noteworthy that inclusion of even a small number of fossils (<10% of the total tips) substantially improves the estimation of both the absolute and relative extinction rates in comparison to analyses of the same data restricted to extant tips only. BAMM’s likelihood is conditioned on the absence of unobserved rate shifts, an assumption that has been criticized in the recent literature (Moore et al. 2016). However, we find no evidence that these unknown quantities affect inference (Fig. 10). Our results are thus consistent with Rabosky et al.’s (2017) demonstration that unobserved rate shifts are unimportant for empirically relevant parameterizations of the diversification process.

Given the preservational biases inherent to the fossil record, our results showing that BAMM is at least somewhat robust to temporal heterogeneity in preservation rates and uncertainty in the number of fossil occurrences are encouraging (Figs. 8 and 9). Changes in the preservation rate through time are likely to be more extreme in real data sets than considered by our study. However, as long as the average preservation throughput time is comparable to values used in our simulations, we expect that the inclusion of fossil data will improve estimates of diversification parameters. Incorrect specification of the number of fossil occurrences biases the magnitude of rate estimates, but the true and estimated rates remain highly correlated even with substantial misspecification of the true number of fossils. This suggests that relative rates within a phylogeny may largely be robust to misspecification of occurrence counts, even if the absolute values of those rates are biased. Nonetheless, assumptions about the nature of fossil preservation and lineage comparability

![Figure 7](https://academic.oup.com/sysbio/article-abstract/68/1/1/4999317)

**Figure 7.** Topological accuracy of inferred shift locations. (a) Marginal posterior probability of each rate shift as a function of the number of tips in the shift regime. A value of 0.50 would imply that 50% of samples from the posterior recovered a shift in the same topological location (e.g., same branch) as the true shift. In general, we expect the marginal shift probability to be somewhat less than 1.0 even for well-supported shifts, because the evidence for a given shift can be smeared across several adjacent branches (Rabosky 2014). Red horizontal lines denote median marginal probabilities of rate shifts within sliding windows of arbitrary size (see text for details). (b) Marginal probability of each rate shift as a function of both the proportional change in speciation rate ($\lambda_{s_{new}}/\lambda_{s_{old}}$) as well as the number of descendant tips in the regime. Darker points represent higher marginal probabilities: Shift locations are inferred with the highest accuracy when large rate increases occur and/or when shifts lead to large numbers of descendant tips. (c) Accuracy with which BAMM infers cohort membership, computed as the mean probability of assigning a given taxon pair to the correct grouping relationship (e.g., “same shift regime,” “different shift regime”). Red points represent the mean cohort accuracy of BAMM analyses across four preservation rates as a function of the number of shifts. Black squares represent the corresponding cohort assignment accuracy expected under random shift placement; see text for details.

![Figure 8](https://academic.oup.com/sysbio/article-abstract/68/1/1/4999317)

**Figure 8.** Performance of BAMM when the assumption of time-homogeneous fossil preservation is violated. Speciation ($\lambda_{s}$, a), relative extinction ($\mu/\lambda_{s}$, b), inferred number of shifts (c) and cohort accuracy (d) are shown for trees fossilized using a stage-specific simulation and analyzed using the constant-preservation rate assumption of BAMM; results illustrate regimes with five or more tips, for comparison to Fig. 2.
between neontological and paleontological datatypes should be treated with caution in future empirical work. In the case of clade-wide mass extinction (Supplementary Fig. S10 available on Dryad), the bias in BAMM’s extinction estimates is easily understood. BAMM has no ability to accommodate mass extinctions directly, but it is nonetheless forced to model a situation where a large number of taxa became extinct at a particular point in time. Hence, the background extinction rate for the focal clade must increase to accommodate the extinction of many taxa, even though the clade may have had low extinction throughout much of its history. In effect, BAMM smears the effects of the mass extinction across earlier periods of time when background extinction was lower.

Because the current implementation of the model does not accommodate time-varying diversification rates, it is possible that resulting time-smeared rate estimates will be an inadequate description of the true diversification process. Similarly, for any clades that have gone extinct in their entirety, net diversification rates will generally be estimated as near zero throughout the history of the clade. This potential for time-averaging of rates is a substantial concern for interpretation that must be considered carefully by users of the method, at least until extensions have been developed that can better accommodate time-varying diversification processes.

**Sampling Biases**

Paleontologists have long recognized that apparent long-term trends in macroevolutionary dynamics can result from biases in the rock record, and in particular the temporal variation in the total amount of sedimentary rock (Raup 1972, 1976; Sepkoski et al. 1981; Foote and Raup 1996; Peters and Foote 2001; Peters 2006; Holland 2016). Even if total species richness is constant through time, intervals with greater amounts of exposed sedimentary rock volume, or with the same amount of rock distributed across a greater geographic extent, will generally appear to be more diverse (Raup 1972). A general trend of increasing preservation potential through time has long been documented (e.g., Raup 1976), and if this trend were universally monotonic it would be relatively easy to model. However, preservation rates have varied geographically throughout Earth’s history (Peters 2005). At any given time in the past, most of the habitable environments that existed are unpreserved. This facet of the rock record becomes particularly problematic when a clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential. If preservation rate for the focal clade endemic to a region either appears or disappears due to a shift in preservation potential.
underlying sedimentology (Kidwell 2005; Foote et al. 2015). The BAMM extension described in this article incorporates a very simple model of preservation, such that users merely need to specify the total number of fossil occurrences associated with the lineages that are included in the phylogeny. Accommodating changes in preservation potential through time, among lineages, and across geographic regions is an obvious future extension for models like BAMM that integrate extant and fossil data.

Comparability of Neontological and Paleontological Data

Many challenges remain in linking palaeontological and neontological data, as the very concept of a lineage differs between the two datatypes. Fossil taxa are identified based on preserved morphological traits, such that that a single fossil morphospecies may be equivalent to multiple biological species that are distinguishable by multiple traits that are unlikely to fossilize (e.g., behavior, coloration, soft-tissue anatomy, vocalizations). Further, it is difficult in the fossil record to discriminate between a single lineage sampled repeatedly through time (a series of anagenetic morphospecies) and multiple, closely-related but separate lineages present in different stratigraphic horizons. Hence, inferences that use method described in this article are subject to an additional source of uncertainty that reflects different species concepts (either in theory or in practice) between neontological and paleontological data.

FIGURE 10. Metrics of within-tree rate accuracy as a function of the proportion of shifts in the tree that are unobserved, for trees with at least 50 observed tips. For the branches in each tree we evaluated the inferred and generating rate of speciation and extinction, calculated the slope (1st and 3rd rows), and Pearson correlation (2nd and 4th rows) between them, and show them relative to the proportion of rate shifts in the tree that have no sampled taxa (see Fig. 1). The relative density of values across all preservation levels is shown to the right. Both metrics for both rates have their highest density across all trees and rate regimes near the optimal value of 1 (mean slopes of 0.67 and 0.41 for speciation and extinction; mean correlations of 0.77 and 0.48 for speciation and extinction). Neither rate shows a relationship between the within-tree metric and the proportion of unobserved shifts suggesting that unobserved shifts do not bias rate estimates in these simulations. Filled circles denote trees where BAMM identified substantial evidence for rate variation (Bayes factor evidence >20 for one or more shifts); open circles are trees that lacked evidence for rate variation. Note that branch-specific slopes and correlations as presented above are expected to equal zero if BAMM fails to detect diversification rate variation (see Rabosky et al. 2017, Fig. 10). For additional visualizations demonstrating the lack of a relationship between performance and unobserved shifts, see the Supplementary Materials available on Dryad.

Comparability of Neontological and Paleontological Data

Many challenges remain in linking palaeontological and neontological data, as the very concept of a lineage differs between the two datatypes. Fossil taxa are identified based on preserved morphological traits, such that that a single fossil morphospecies may be equivalent to multiple biological species that are distinguishable by multiple traits that are unlikely to fossilize (e.g., behavior, coloration, soft-tissue anatomy, vocalizations). Further, it is difficult in the fossil record to discriminate between a single lineage sampled repeatedly through time (a series of anagenetic morphospecies) and multiple, closely-related but separate lineages present in different stratigraphic horizons. Hence, inferences that use method described in this article are subject to an additional source of uncertainty that reflects different species concepts (either in theory or in practice) between neontological and paleontological data.
How Many Fossil Occurrences?

The model we have implemented assumes that fossil occurrences are generated under a simple birth–death–fossilization process, which implies that occurrences represent the sampling of a specific lineage at a specific point in time. We suggest that the number of occurrences should reflect the number of temporally-unique occurrences of identifiable lineages, or the number of stratigraphically unique occurrences of both extinct and extant species-level taxa that are included in the phylogeny. The number of temporally-unique identifiable occurrences differs from raw counts of the total number of fossil occurrences of the clade in several important ways. In BAMM, taxonomically indeterminate records belonging to a clade (e.g., “Aves indet.”) should not be used, as there is no way to know whether the fossil corresponds to an observed lineage within the focal clade (either an extinct or extant form represented by a lineage on the phylogeny), or if it belongs to an as-yet unrecognized branch within the clade (e.g., a new species not yet included in the phylogeny). Assuming we are generally working with species-level phylogenies, one should also avoid using occurrences that have not been resolved below the genus level in BAMM, as they might represent lineages that are not present in the tree. Furthermore, multiple individuals of the same species collected from a single bone or shell bed should be treated as a single occurrence.

As an example of how researchers might specify an appropriate number of fossil occurrences for a BAMM analysis, we will consider how occurrences might be tabulated for a recent phylogenetic study of extant and extinct canid mammals (Matzke and Wright 2016). A simple search (17 February 2017) on “Canidae” from the Paleobiology Database (Alroy et al. 2001; Varela et al. 2015) gave at least 10,660 fossil observations (unique records). Of this set, 2946 represented stratigraphically unique occurrences, and 2107 of those observations were resolved to the species level. The data set analyzed by Matzke and Wright (2016) contains 142 species-level taxa, and we identified 1837 stratigraphically-unique occurrences of those taxa in the database. For the simple (time-homogeneous) preservation model described in this article, we would specify 1837 occurrences for a BAMM analysis of the canid phylogeny. The Paleobiology Database allows rapid searching for occurrences that match only the set of taxa present in a given phylogeny, and querying the output for duplicate localities can be done quickly (see Dryad scripts for our horse example).

At present, the model assumes that fossil occurrences are comparable through time and across clades. This assumption is clearly violated in practice, particularly when we consider large clades whose constituent species differ in key biological traits that influence their probability of preservation. To illustrate this point, consider isolated vertebrate teeth, a common type of fossil. Crocodilians shed their teeth continuously through life, although their teeth are rarely identifiable to the species level. On the other hand, mammals only have two sets of teeth in their life, so they produce fewer fossils, but each tooth is far more likely to be mapped to an observed lineage on a phylogeny. These differences make it difficult to equate the occurrence of a single crocodilian tooth to the occurrence of a mammalian molar. An obvious extension to the modeling framework presented here will be to incorporate lineage-specific variation in preservation rates, which will help account for such clade-specific differences in preservation potential.

**CONCLUSIONS**

The fossilized birth–death process has already shown great promise for inferring and time-scaling phylogenies...
using all available evidence. Recent advances in extending the model to incorporate piece-wise time variation (Gavryushkina et al. 2014, 2017) and non-uniform incomplete sampling (Zhang et al. 2016) have greatly improved the ability to estimate phylogenies that include both extinct and extant lineages. Herein, we have shown that BAMM performs well on dated phylogenies that include a mix of extinct and extinct tips (or extinct-only tips), providing a useful tool for characterizing diversification rate variation across the expanding pool of time-calibrated phylogenies that include extinct lineages. This approach will help researchers test hypotheses about macroevolutionary rate control in clades that may lack sufficient fossil data for non-phylogenetic (occurrence-only) paleobiological inferences.

The results of this study and others (e.g., Didier et al. 2012) demonstrate that the inclusion of fossil data improves the estimation of both speciation and extinction rates from phylogenies. The assumptions of the model we describe are simplistic, and numerous challenges remain to be addressed. However, we have found that results are reasonably robust to several key violations of model assumptions. The method described here is a first step toward integrating information from paleontological and neontological data sets to better understand the extent to which the dynamics of species diversity have varied through time and among lineages.
