ABSTRACT: The synthesis of charged polymers often requires the polymerization of protected monomers, followed by a polymer-analogous reaction to the polyelectrolyte product. We present a mild, facile method to cleave tert-buty1 groups from poly(tert-buty1 acrylate) blocks that yields poly(acrylic acid) (pAA) blocks free of traces of the ester. The reaction utilizing a slight excess of HCl in hexafluoroisopropanol (HFIP) at room temperature and runs to completion within 4 h. We compare deprotection in HFIP with the common TFA/DCM method and show that the latter does not yield clean pAA. We show the effect of complete tert-buty1 cleavage on a ABA triblock copolymer, where poly(N-isopropylacrylamide) (pNIPAM) is A and pAA is B, by means of viscosimetry, DLS, and SAXS on solutions above overlap. The pNIPAM blocks dehydrate, and their increased self-affinity above the lower critical solution temperature (LCST) results in network formation by the triblocks. This manifests itself as an increase in viscosity and a slowing down of the first-order correlation function in light scattering. However, this stickering effect manifests itself exclusively when the pAA block is tert-buty1-free. Additionally, SAXS shows that the conformational properties of tert-buty1-free pAA copolymers are markedly different from those with residual esters. Thus, we illustrate a surprising effect of hydrophobic impurities that act across blocks and assert the usefulness of HCl/HFIP in pAA synthesis.

INTRODUCTION

Acrylic acid (AA) is the smallest unsaturated carboxylic acid and can be polymerized radically. By virtue of the carboxylic moiety, the resulting polymers are polyelectrolytes and have a pH-dependent charge and H-bonding capacity. In copolymers, AA is used to tailor responsive behavior of other polymeric building blocks, such as the swelling of hydrogels and the lower critical solution temperature (LCST) of poly(N-isopropylacrylamide) (pNIPAM) and its copolymers. pNIPAM is one of the most studied polynions in polyelectrolyte complexes, owing to its ability to form complexes with many polycations.

In radical polymerizations, acrylic acid is unusually inclined to transfer reactions to solvent, transfer to polymer, and formation of Michael dimers. These side reactions result in diminished control over linearity, molecular weight distribution, and end-group fidelity of the polymer products. There are many reports that detail pAA synthesis with the help of controlled radical polymerization (CRP) techniques, in particular reversible addition—fragmentation chain transfer (RAFT). Chain transfer agents are known to reduce branching and termination by ensuring a low concentration of active radicals. Nonetheless, it is difficult to prepare strictly linear polymers directly from AA due to its high rate and extensive repertoire of side reactions, and branching is often overlooked in reports on pAA. Given the difficulties of direct polymerization of AA, pAA is often made in a two-step process starting from a precursor monomer that is less affected by transfer reactions, followed by a polymer-analogous reaction that yields pAA.

A canonical two-step method relies on the ester of acrylic acid and tert-butanol, the latter acting analogously to a protecting group. tert-Butyl acrylate (tBuAc) can be polymerized by anionic or radical means, and the resulting polymer is de-esterified into pAA under acidic conditions, trifluoroacetic acid in DCM (TFA/DCM) being especially common. However, even a strong molar excess yields pAA with at most 99.5% liberated carboxylic acid, the rest being still
esterified with tert-butanol. The incomplete cleavage remains unaddressed, even though residual tert-butyl groups can affect polymer properties. Foreseeable effects are an increase of surface pressure at water–apolar interfaces and a greater tendency to form complexes through hydrophobic interactions, since the resulting structures are comparable to hydrophobically modified pAA. Thus, a means of obtaining ester-free pAA from pBuAc is desirable.

In the present work, we report a cleavage reaction that yields quantitatively de-tert-butylated pAA rapidly, based on the work of Palladino and co-workers. We apply the method to the synthesis of a triblock copolymer with a monomer that is representative of the use of pAA in the literature, pNIPAm. Full tert-butyl ester cleavage is shown by NMR. To assert the necessity of complete deprotection of pBuAc precursors, we show that the ubiquitous TFA/DCM conditions yield polymers with markedly distinct flow and conformational properties, as witnessed by viscosity, dynamic light scattering (DLS), and small-angle X-ray scattering measurements (SAXS).

## Experimental Section

### Materials.

2,2'-Azobisisobutyronitrile (AIBN, 98%), N-isopropylacrylamide (NIPAm, 97%), tert-butyl acrylate (tBuAc, contains 10–20 ppm monomer ethyl hydroquinone as inhibitor, 98%), trioxane (≥99.9%), trifluoroacetic acid (TFA, ≥99%), concentrated HCl (37% solution in water), and dioxane (anhydrous, 99.8%) were obtained from Sigma-Aldrich, Germany, and used without further purification unless noted otherwise. pNIPAm was recrystallized twice from a mixture of hexane and acetone. tBuAc was passed over a short column of Al2O3 to remove the inhibitor. AIBN was recrystallized thrice from MeOH. Bis(2-methylpropionic acid)-trithiocarbonate (BMAT) and BMAT-terminated pNIPAm were synthesized as described in the literature, with NMR and SEC characterization described in Table S1. Hexafluoroisopropyl alcohol (HFIP, AR), dichloromethane (DCM, AR), tetrahydrofuran (THF, HPLC-grade), and methanol (MeOH, HPLC) were obtained from Biosolve, France.

### Synthesis of pNIPAm-b-pBuAc-b-pNIPAm.

A Schlenk flask was charged with a solution of BMAT-terminated pNIPAm (0.581 g, 0.104 mmol), tBuAc (5.3 g, 41.4 mmol), AIBN (3.4 mg, 0.020 mmol), and trioxane (0.372 g, 4.14 mmol) in dioxane (21 mL) and was subjected to five freeze–pump–thaw cycles. The solution was magnetically stirred at 70 °C for 45 min, after which the polymerization was stopped by admitting atmosphere into the flask while cooling on an ice bath. The material was precipitated thrice in ice-cold MeOH:water 3:1 and dried under high vacuum.

### TFA/DCM Deprotection of pNIPAm-b-pBuAc-b-pNIPAm.

pNIPAm-b-pBuAc-b-pNIPAm (1.05 g, 0.023 mmol) was dissolved in DCM (50 mL) in a round-bottomed flask, to which was added 6 equiv of TFA (4.2 g, 39 mmol) with respect to the amount of tBu units. The mixture was stirred for 72 h at room temperature; the precipitated product was washed with fresh DCM and extensively dried under high vacuum. The dry polymer was dispersed in water and titrated with an NaOH solution until the solution was neutral. Water was removed by freeze-drying. This yielded pNIPAm-pBuAc-b-pNIPAm as a white, fluffy powder.

### HCI/HFIP Deprotection of pNIPAm-b-pBuAc-b-pNIPAm.

pNIPAm-b-pBuAc-b-pNIPAm (3.5 g, 0.093 mmol) was dissolved in HFIP (314 mL) in a round-bottomed flask, to which concentrated HCl (37% 2.6 mL, 31.4 mmol) was added, 1.3 equiv with respect to the amount of tBu units. After 4 h, the mixture was stripped of volatiles, and the dry polymer was dispersed in water and titrated with an NaOH solution until the solution was neutral. A slight cloudiness was removed by centrifugation at 15000g, and the supernatant was dehydrated by freeze-drying. pNIPAm-b-pAA-b-pNIPAm was recovered as a white fluffy powder.

### Polymer Characterization.

1H and 13C NMR measurements were performed on a Bruker AVANCE 400 spectrometer. Fourier transform infrared absorption spectra were collected on a Bruker PLATINUM ATR mounted into a TENSOR spectrometer on powdered sample. A background was taken and subtracted from the spectra, followed by baseline correction and transformation from transmission to absorption.

### Size-Exclusion Chromatography (SEC).

SEC of pNIPAm and its copolymers with pBuAc was done on a Agilent 1200 HPLC equipped with a PLgel 5 μm Mixed-D column with RI detection, calibrated with polystyrene standards, and HPLC-grade THF as eluent. The presence of pNIPAm blocks complicates the analyses due to column–analyte interactions. The problem is somewhat remedied in an aqueous SEC system on corresponding de-tert-butylated products. Aqueous size exclusion chromatography of pAA copolymers was done in an aqueous buffer of 0.01 M Na2HPO4/NaH2PO4 with 0.1 M NaNO3 on an Agilent 1260 Infinity II HPLC equipped with a Waters Ultrahydrogel 500 column for molecular weight analysis. Analytes were detected with a refractive index detector and by UV adsorption.

### Trithiocarbonate Cleavage with Hydrazine.

In adaptation of a previous report, the salt of BMAT-derived triblock pNIPAm-pAA-b-pNIPAm (0.100 g, 3.34 μmol of trithiocarbones) was dissolved in water (11 mL), to which was added 5 equiv of hydrazine (1 μL, 16.7 μmol). The mixture was stirred at room temperature for 72 h, and an aliquot was diluted 1:3 with 0.01 M Na2HPO4/NaH2PO4, which was analyzed with SEC against an Agilent PL AquaGel-OH 8 μm column and compared with an aliquot of nontreated sample.

### DLS of Triblock Solutions.

DLS measurements on triblock networks were performed in the manner described by Bohdan et al. An ALV light scattering apparatus equipped with a 632.8 nm JDSU 1145P laser and a LSE-5004 correlator was used. Temperature was controlled by means of a Julabo water bath. DLS measures the electric field autocorrelation function g(1)(t) from which the normalized first-order correlation function g(2)(t) is obtained:

\[ g(2)(t) = \beta^{1/2} g(1)(t) \]

In which β is a geometry-dependent constant close to unity. We describe g(1)(t) by a two-mode stretched exponential decay:

\[ g(1)(t) = \sum_{i=1}^{2} A_i \exp \left( -\frac{t}{\tau_i^{\alpha}} \right) \]

where \( \tau \) is the exponential decay time and \( \alpha \) is the stretch parameter. The latter characterizes the width of the decay time distribution, with \( \alpha = 1 \) corresponding to a simple exponential decay and smaller values to a more stretched shape, and thus a broader decay time distribution. The subscripts \( f \) and \( s \) refer to respectively the fast and slow modes that we observe for all relaxations.

### Rheology of Triblock Solutions.

Rheological measurements were recorded on an Anton Paar MCR-301, using a 1 mL Couette geometry and temperature control by a Peltier system. Evaporation was avoided by the use of a tetradecane-filled solvent trap. Viscosities were measured by monitoring stress as a function of shear rate between 0.01 and 1000 s⁻¹.

### Small-Angle X-ray Scattering of Triblock Solutions.

Small-angle X-ray scattering experiments were performed on a SAXS/LAB Ganesha 300 XL setup with a GeniX-Cu ultralow divergence source with a wavelength of 1.54 Å and a flux of 10⁻⁸ 1 and a Pilatus 300K silicon pixel detector with 487 × 619 pixels of 172 × 172 μm². Temperature was controlled between 20 and 60 °C with a Julabo temperature controller. Three detector distances were used, resulting in a q-range of 0.001−1 Å⁻¹. Aqueous 292 mg mL⁻¹ samples were prepared with 1 mL water to 292 mg of polymer and were filtered over 0.2 μm regenerated cellulose (RC) syringe filters after dissolution. Correlation curves were recorded for times between 3000 and 10000 s to ensure full decay of \( g(1)(t) \), with higher temperatures resulting in slower decays.
introduced into 2 mm quartz capillaries, heated to 60 °C, equilibrated for 2 h, and then measured for 1800 s at three different detector distances. This was repeated for 40 and 20 °C. The diffusion patterns were azimuthally averaged, and intensities were corrected for transmission, sample thickness, and detector distance. Finally, scattering from water-filled capillaries corrected in the same fashion was subtracted from the scattering of triblock solutions.

## RESULTS AND DISCUSSION

We prepare pNIPAm-b-pAA-b-pNIPAm (NAN) triblock copolymers from pNIPAm-b-\textit{t}BuAc-b-pNIPAm (NTN) precursors, as shown in Figure 1 and further detailed in the Supporting Information (Figures S1 and S2). One common \textit{t}Bu-carrying precursor N_{24}-T_{330}-N_{24}, where $N_{24}$ denotes a pNIPAm block length of 24 monomers and $T_{330}$ denotes a \textit{t}BuAc block length of 330 monomers, serves to compare two acidic ester cleavage reactions: stirring with 6 equiv of TFA in DCM for 72 h and with 1.3 equiv of HCl in HFIP for 4 h. The times are sufficiently long to preclude any further reaction. For TFA/DCM, we choose conditions similar to previous reports on pAA synthesis\textsuperscript{12−17} to allow comparison to a situation that is typical in the field.

NMR spectroscopy on aliquots from the reaction mixtures in MeOD shows resonances characteristic of the NIPAm pendant groups at 1.16 and 3.97 ppm, as seen in the NMR spectra of Figure 2a. Contributions of the \textit{t}Bu peak appear at 1.47 and 1.48 ppm, as the dominant peak in NTN precursor, and as a well-noticeable contribution for the TFA-deprotected NAN, even after 72 h. Contrarily, in the HCl-treated case, the residual \textit{t}Bu peak is sufficiently small to be indistinguishable from the tacticity features of the backbone protons, which are well-resolved in MeOD. Save for the resonances attributed to residual \textit{t}Butyl, the polymeric contributions to the spectra are identical, indicating no other changes to the chemical structure than \textit{de-t}-butylation.

In Figure 2b, the resonances of backbone and \textit{t}Bu are enlarged, robustly confirming the disappearance of the latter in the case of HCl/HFIP after 3 h. We note that the often-used D$_2$O does not provide an adequate environment for the \textit{t}Bu groups to give a sharp signal and thus leads one to underestimate its presence.

Deconvolution of the spectra between 1.4 and 1.8 ppm allows to separate the \textit{t}Bu contribution from the backbone singlets by fitting each peak with a Gaussian−Lorentzian...
function. Figure 2c shows a representative case. A comparison of the N-isopropylmethine signal at 3.97 ppm to the tBu contribution at 1.47 ppm gives the deprotection efficiency $\phi_D$ according to

$$\phi_D = 1 - \frac{1}{2} \frac{A_{tBu}}{A_{Nim}} \frac{DP_N}{DP_T},$$

where $A_{tBu}$ and $A_{Nim}$ are the integrals under the deconvoluted tBu contributions and the N-isopropylmethine signals, and DP is the degree of polymerization of the block denoted in subscript. This procedure thus provides accurate values for $\phi_D$, even in cases where the area under the tBu region is dominated by backbone signals.

Given the improved rate and extent of the reaction, we strongly recommend deprotection with HCl/HFIP above TFA/DCM, with deprotection efficiencies of $>99.9\%$ for HCl/HFIP and $90–98\%$ for TFA/DCM. We summarize the deprotection efficiencies $\phi_D$ of the two methods in Table 1.

“Block lengths are based on theoretical molecular weight $M_0$ that is based on monomer conversion. $M_n$ and $D$ are calculated from SEC traces after elution in 0.01 M aqueous phosphate buffer at pH 7 with 0.1 M NaNO₃. Entries marked with an asterisk are used further on in a comparative study of flow behavior, DLS relaxation times, and SAXS.

The entries marked with an asterisk are used for a comparison of flow properties and DLS relaxation times (vide infra). As seen in Table 1, HCl/HFIP achieves full tert-butyl removal down to 1.0 equiv of HCl. We note that the polymeric contributions to the NMR spectra of all HCl/HFIP-derived products were identical for all acid loadings. Additionally, Table 1 shows deprotection and aqueous SEC characterization data for runs on further NAN structures with slightly varied block lengths. FT-IR data are given in the Supporting Information (Figure S3).

We use aqueous SEC to confirm the triblock identity of our compounds and therefore the stability of the thirticarbonic bond under conditions of deprotection and subsequent hydrolysis. We find similar values of $M_0$ for both TFA- and HCl-deprotected species, as can be seen in Table 1. Additionally, we intentionally cleaved a sample of N24-A330-N24 using hydrazine. Treatment with hydrazine resulted in a discoloration of the sample and a reduction of $M_0$ by a factor of 2, as shown in Figure S4. Thus, the triblocks are quantitatively cleavable, which shows that the thirticarbonate is stable, even after deprotection and neutralization to pH 7.

We argue that two factors improve the pBuAc de-esterification efficiency of HCl/HFIP with respect to TFA/DCM. DCM is not a solvent for pAA, which prevents contact between the partially deprotected intermediates (essentially pAA/pBuAc copolymers) and the acidic medium. In addition, carboxylates form dimers in apolar environments, further decreasing contact. Our results are not meant to capture the respective contributions of both factors; however, it is clear that TFA/DCM cannot be recommended for the synthesis of highly defined pAA. Because HFIP does not precipitate the product and since HCl is a non-carboxylic acid, both issues are not at play for HCl/HFIP de-tert-butylation.

Literature abounds with reports on properties of pAA (co)polymers derived from pBuAc. We now turn to the question whether tert-butyl moieties influence the solution properties of our copolymers strongly, even when present at the level we found for TFA/DCM. To this end, we studied the difference in the DLS relaxation time and viscosity of aqueous solutions above overlap between triblocks cleaved with TFA and HCl, derived from a common NTN precursor, N26-T318-N36. A common NTN precursor ensures a constant chain length between the two polymers. The NTNs employed in the comparison are labeled with an asterisk in Table 1. In addition, SAXS was used to inquire into structural differences in HCl/HFIP and TFA/DCM products, N24-(A297-T33)-N24 where the center block in the latter is the incompletely cleaved pBuAc center block. Additionally, we compared two HCl-deprotected structures of different block lengths, N24-A220-N36 and N24-A330-N24.

At a weight concentration of 292 mg mL⁻¹ without added salt, all polymers dissolved within 2 days on a shaking bench. Based on an estimate for $R_C$ of 5 nm taken from DLS measurements of dilute solutions at high salt (data not shown), the overlap concentration is below 90 mg mL⁻¹ for all triblocks in demineralized water. Thus, our solutions strongly exceed overlap. When heated to 60 °C, which is well above the bulk LCST for pNIPAm homopolymer around 32 °C, both solutions remain transparent. This is in marked contrast to the rapid increase in turbidity that is observed for diblock solutions with a charged block and an LCST block, where the turbidity increase is attributed to formation of micelles due to the association of pNIPAm blocks above the LCST. Solutions of HCl-cleaved N24-A330-N24 remain transparent even after being heated to 60 °C for 3 days and show a decrease in scattering intensity at 90° when heated to 40 and 60 °C (Figure S5), precluding micellization. Under identical conditions, the TFA-cleaved N24-(A297-T33)-N24 solutions develop some turbidity and show occasional spikes in scattering intensity. However, SAXS measurements (vide infra) again preclude micellization as a cause. DLS measurements on dilute (5 mg mL⁻¹) triblock solutions show no changes in count rate or correlation times upon heating from room temperature to 60 °C, and thus show no evidence of micellization, due to the very short sticker length and high osmotic pressure due to the charged blocks.
When heated from 15 to 60 °C, a 292 mg mL⁻¹ solution of N₂₄⁻A₅₀⁻N₂₄ shows a strong increase in viscosity, whereas none is visually distinguishable for solutions of N₂₄⁻(A₉₀⁻T₃₅)-N₂₄. This behavior is quantified in Figure 3 (left) by means of rotational rheology in a Couette geometry, where we plot the shear-rate-dependent viscosity for both triblocks, at T above and below the bulk LCST of pNIPAm homopolymer. All viscosity curves are characterized by a wide Newtonian range, and the Newtonian viscosity of the sample increased 70-fold for N₂₄⁻A₃₀⁻N₂₄, whereas the increase is marginal for the case of N₂₄⁻(A₉₀⁻T₃₅)-N₂₄.

We stress that our solutions, upon heating, neither undergo a macroscopic phase transition nor have a cloud point. We employ DLS to study the slowed-down relaxation of a transient network. Exactly the effect of the collapse of pNIPAm as the temperature is increased over more than 2 orders of magnitude. Its TFA-cleaved counterpart has a more rapid relaxation of the slow mode and shows only modest growth with temperature.

The three-mode stretched exponential relaxation of g₁(t) in DLS measurements of transient polymer networks has been previously described by other authors,²³,²₄ where poly(ethylene glycol) networks were formed by association of aliphatic chains, which were attached to the polymers at either one or both ends, yielding “diblock” or “triblock” structures. The three-mode stretched exponential relaxation of g₁(t) in transient polymer networks has been previously described by other authors,²³,²₄ where poly(ethylene glycol) networks were formed by association of aliphatic chains, which were attached to the polymers at either one or both ends, yielding “diblock” or “triblock” structures. The relaxation times of the second mode increased strongly with increasing proportion of triblock structures (thus increasing network connectivity) and is ascribed to increased node residence times. Thus, this connectivity increase is analogous to a temperature increase in our experiment. The r of the third mode is reported to show an even stronger connectivity dependence²³ and is ascribed to diffusion of associated clusters.

Similarly, we attribute the increase of η and τ, with T to a prolongation of the mean residence time of pNIPAm stickers in the nodes, driven by a higher segregation tendency. The collective effect of the increased residence time is a slowing down of the transient network. The wavevector q is 0.019 nm⁻¹, which means that we are at length scales 1 order of magnitude beyond the node–node correlations. Nonetheless, while τ cannot be trivially converted to a residence time, the relaxation time must necessarily increase with residence time.²³ We convey the relaxation of these transient networks in Figure 5—one must realize that the temperature and the extent of deprotection determine the τ over which we would observe relaxation.

Figure 3. Shear-rate-dependent viscosity of 292 mg mL⁻¹ solutions of N₂₄⁻(A₉₀⁻T₃₅)-N₂₄ (squares) and N₂₄⁻A₃₀⁻N₂₄ (circles) at 15 °C (blue) and 60 °C (red).

Figure 4. (a) First-order correlation functions from DLS on 292 mg mL⁻¹ solutions of N₂₄⁻A₅₀⁻N₂₄ (squares) and N₂₄⁻(A₉₀⁻T₃₅)-N₂₄ (circles) at 20 °C (blue), 40 °C (orange), and 60 °C (red). The lines are fitted using eq 2. (b) Characteristic slow and fast relaxation times τₚ and τₛ as a function of temperature as fitted using eq 2. The lines are intended as a guide to the eye.
It is remarkable that the availability of hydrophobic groups decreases the residence time, since it could be argued that the hydrophobic effect would be stronger with the participation of such groups and thus sticker association more prominent. However, we speculate that the residual esters actually improve compatibility between the pNIPAm and the pAA blocks, which results in weakening of the physical cross-links. Additionally, it could be argued that the coils slightly shrink causing them to overlap less. This is consistent with the lower viscosity of the N24-(A297-T33)-N24 solution at low temperatures and more prominent participation of a fast mode at room temperature.

Additional clues for the origin of short sticker residence times for identical pNIPAm moieties connected to more strongly hydrophobically contaminated pAA come from SAXS, which reveals time-averaged density fluctuations, thus structural information rather than r-dependent observables. Here, we compare the angle-dependent absolute scattering intensities \( d_\text{node} = 292 \text{ mg mL}^{-1} \) solutions of the tert-butylated N24-(A297-T33)-N24 and fully liberated triblocks N36-A220-N36 and N24-A130-N24 at 20, 40, and 60 °C. All scattering intensities are peaked in the vicinity of \( q^* = 0.03 \text{ Å}^{-1} \), as is visible in Figure 6. The peaks sharpen and shift to smaller \( q \) with \( T \), which suggests their origin to be density fluctuations due to increased nonsolubility of pNIPAm with a corresponding internode distance \( d_\text{node} \). Indeed, a change occurs between 20 and 40 °C, in agreement with an LCST of 32 °C. We attribute the presence of an internode peak below the LCST to pNIPAm–pNIPAm interactions that have been observed in scattering studies of aqueous pNIPAm before, which note a decrease in excluded volume starting already from 5 °C and a consequent clustering below the LCST.36

Upon heating from 20 to 60 °C, the internode distance \( d_\text{node} \) that correspond to \( q^* \), at which \( dq/\partial t \) passes through a prominent maximum, increases from 18.5 to 20.4 nm for N36-A220-N36. Thus, the pAA bridges are stretched to approximately twice their diameter of 10 nm, costing approximately one \( k_B T \) assuming entropic elasticity. For N24-A130-N24 \( d_\text{node} \) is between 19.3 and 21.9 nm, in line with its longer pAA block. In other words, the six curves for HCl-derived NAN structures are highly similar, suggesting that the qualitative picture in Figure 5 is correct for all cases and that the chemistry and temperature merely cause changes in the internode distance and sticker residence time of the transient network.

The TFA-deprotected N24-(A297-T33)-N24 shows smaller values of \( d_\text{node} \) between 17.6 and 19.7 nm, corresponding to a lesser stretching of the polyelectrolyte block due to more compatibility with the pNIPAm moieties. A striking feature of the curves is the high-q region, where all curves show power laws of, in the case of N24-(A297-T33)-N24, \( q^{-2/3} \), and, in the case of fully liberated samples, \( q^{-5/3} \), the latter corresponding to a self-avoiding walk.37 We observe these forms up to a \( d \) of 1.5 nm, and starting from 5.4 nm for TFA and around 2 nm for the HCl-derived samples, where scattering is dominated by chain statistics (\( R_g > d > \lambda_b \)).

At present, we have no interpretation of the \( q^{-2/3} \) scaling for the TFA-treated case. Clearly, it is not reasonable to attribute it to an even further stretching of the chains than we would expect for a rod (\( q^{-1} \)). Thus, the observed shape is likely due to a superposition of different dependencies in the high-q scattering. Nonetheless, we stress that the high-q data witness that TFA leaves us with pAA blocks that have strongly altered compatibility with the pNIPAm moieties. A striking feature of the curves is the high-q region, where all curves show power laws
conformational properties with respect to pure pAA blocks. Whereas the structure on the internode length scale is only weakly dependent on temperature and chemistry, the density fluctuations on the chain length scale are strongly altered by tert-butyl moieties incompletely cleaved by TFA.

Through DLS, rheology, and visual observations of NANN triblocks around RT and at 60 °C, we observe a significant enhancement of sticker residence times of pNIPAm blocks when the tert-butyl group is removed completely, whereas association seems to be minimal when hydrophobic groups have presence. SAXS reveals internode distances of around twice the dilute coil diameter that increase slightly with pAA chain length and absence of hydrophobic groups. More strikingly, the density fluctuations on the chain length scales are dramatically different in the case when tert-butyl groups are not completely removed. Thus, the presence of these groups has a strong effect on the self-assembly behavior of NANN copolymers, which are prepared throughout literature through a method that we show does not remove tert-butyl up to an extent that their influence is negligible.

**CONCLUSION**

In summary, we report a facile, rapid de-tert-butylation scheme for the synthesis of pAA block copolymers with pNIPAm from the corresponding copolymer with pBuAc. The action of stoichiometric HCl on a HFIP solution of the tert-butylated precursor yields pAA blocks of a chemical purity that has been inaccessible via the commonly used TFA/DCM mixture. In addition, we show that the presence of residual tert-butyl moieties, at a degree tolerated by the latter method, impacts the aqueous self-assembly properties of these polymers to such an extent that the thermothickening effect due to LCST-driven pNIPAm association is essentially disabled for polymer solutions significantly above overlap. Thus, HCl/HFIP is an essential tool in the study of the aqueous association of pAA copolymers derived from their tert-butylated precursors.
