Niemann-Pick type C1 (NPC1) disease is caused by a deleterious mutation in the Npc1 gene, causing lysosomal accumulation of unesterified cholesterol and sphingolipids. Consequently, NPC1 disease patients suffer from severe neurovisceral symptoms which, in the absence of effective treatments, result in premature death. NPC1 disease patients display increased plasma levels of cholesterol oxidation products such as those enriched in oxidized low-density lipoprotein (oxLDL), a pro-inflammatory mediator. While it has been shown that inflammation precedes and exacerbates symptom severity in NPC1 disease, it is unclear whether oxLDL contributes to NPC1 disease progression. In this study, we investigated the effects of increasing anti-oxLDL IgM autoantibodies on systemic and neurological symptoms in an NPC1 disease mouse model. For this purpose, Npc1 1 mice were immunized with heat-inactivated S. pneumoniae, an immunogen which elicits an IgM autoantibody-mediated immune response against oxLDL. Npc1 1 mice injected with heat-inactivated pneumococci displayed an improved hepatic phenotype, including liver lipid accumulation and inflammation. In addition, regression of motor skills was delayed in immunized Npc1 1. In line with these results, brain analyses showed an improved cerebellar phenotype and neuroinflammation in comparison with control-treated subjects. This study highlights the potential of the pneumococcal immunization as a novel therapeutical approach in NPC1 disease. Future research should investigate whether implementation of this therapy can improve life span and quality of life of NPC1 disease patients.

Keywords: Niemann-Pick type C1, oxidized low-density lipoprotein, pneumococcal immunization, inflammation, lipid metabolism
INTRODUCTION

Niemann-Pick type C1 (NPC1) disease is a rare, fatal disorder caused by mutations in the Npc1 gene which result in the accumulation of unesterified cholesterol and glycosphingolipids in late endosomes/early lysosomes (1–3). The earliest clinical findings of NPC1 disease are mostly related to systemic problems in the liver (neonatal jaundice, liver failure (4–6)) and the spleen (splenomegaly and severe abdominal pain resulting in splenectomies (7), and increased sensitivity to spontaneous infections (8)). While, in most patients, the systemic symptoms resolve over time, some develop severe systemic problems resulting in premature death (4). Besides the systemic manifestation of the disease, NPC1 disease is also characterized by severe disturbances in the central nervous system leading to the progressive impairment of motor and cognitive function (2). In spite of significant advances in the development of therapeutic interventions for NPC1 disease (9, 10), there is currently no curative treatment available.

While lysosomal lipid accumulation is at the root of NPC1 disease, secondary pathological mechanisms such as oxidative stress (11), apoptosis (12), and inflammation (13, 14) have been shown to accompany and even contribute to NPC1 disease progression. Similarly, atherosclerosis and non-alcoholic steatohepatitis (NASH) also feature the aforementioned disease mechanisms (15, 16) and lysosomal lipid accumulation in macrophages (17). These observations suggest a mechanistic link between the pathological mechanisms of NPC1 disease, atherosclerosis, and NASH. Of note, increasing anti-oxLDL IgM autoantibodies levels in the latter metabolic diseases ameliorates the macrophage-mediated inflammatory reaction (18–20). Relevantly, multiple research papers have described the cholesterol oxidation products 7-ketocholesterol and cholestane-3β, 5α, 6β-triol, two products abundantly present in oxLDL (21, 22), as sensitive and specific blood-based biomarkers for diagnosing NPC1 disease (6, 23, 24). However, whether these cholesterol oxidation products contribute to NPC1 disease progression has to our knowledge never been investigated.

Given the mechanistic overlap between the pathologies of NPC1 disease and of the metabolic diseases atherosclerosis and NASH, the aim of the current study was to determine whether increasing anti-oxLDL IgM autoantibodies reduces NPC1 disease symptoms. For this purpose, Npc1n1h mice were immunized with heat-inactivated Streptococcus pneumoniae. Npc1n1h mice are a well-established NPC1 disease model in which a mutation in Npc1 leads to NPC1 truncation and loss of function (25). This mouse model recapitulates some of NPC1 disease most prominent features, including severe lysosomal cholesterol accumulation in most organs and motor function deficits (26–30). Immunization of mice using inactivated S. pneumoniae has been established as an effective approach to increase serum titers of anti-oxLDL IgM autoantibodies by means of molecular mimicry (18, 31). In line with our hypothesis, immunized Npc1n1h mice showed reduced motor function decay over time, decreased neuroinflammation, and degeneration, reduced inflammation in liver and spleen and an improvement in liver lipid metabolism. These findings provide evidence for the involvement of anti-oxLDL IgM autoantibodies in NPC1 disease progression and highlight vaccination strategies leading to the elevation of anti-oxLDL IgM titers as a promising therapeutic approach to reduce NPC1 disease symptoms.

MATERIALS AND METHODS

Preparation of Immunogen

For immunization, the heat-inactivated R36A strain of S. pneumoniae (Birmingham, AL) was used, still bearing the PC headgroup epitope similar to oxLDL. Colonies of the R36A strain were harvested at mid-log phase after incubation at 37°C on blood agar plates and transferred to Todd-Hewitt plus 0.5% yeast broth. The mid-log phase is characterized by an optical density (OD) value of 0.425–0.45 at 600 nm. S. pneumoniae were heat-inactivated at 60°C for 30 min; afterwards, no colonies of this suspension were detected on blood agar plates, thus confirming their inactivation. For freezer stocks of strain R36A, small aliquots of S. pneumoniae at mid-log density were harvested and suspended in Todd-Hewitt plus 80% sterile glycerol and stored at −80°C (32).

Mice and Immunization

Npc1n1h mice were housed under standard conditions and were given free access to food and water. A complementary experiment with age-matched wildtype mice was performed to confirm the phenotypical effect of the Npc1 mutation in Npc1n1h mice. Experiments were performed according to Dutch laws and were approved by the Animal Experiment Committee of Maastricht University. Npc1n1h mice were derived from heterozygous founders (C57BL/6 / Npc1n1h).

The immunization protocol started in 2-week old Npc1n1h mice (male or female) fed a normal chow diet. Mice were divided into 2 groups (n = 12 for both groups). One of the groups received the equivalent of 108 colony-forming units of heat-inactivated pneumococcal immunogen emulsified in 200 μl of sterile 0.9% NaCl for the primary subcutaneous immunization; subsequently, two intraperitoneal booster immunizations were administered every 2 weeks (31). The control group received NaCl injections. During the experiment, which lasted 5 weeks in total, mice were given a normal chow diet. Blood from the tail vein was collected at week 3 and 5. An overview of this suspension were detected on blood agar plates, thus confirming their inactivation. For freezer stocks of strain R36A, small aliquots of S. pneumoniae at mid-log density were harvested and suspended in Todd-Hewitt plus 80% sterile glycerol and stored at −80°C (32).

Abbreviations: NPC1, Niemann-Pick type C1; NASH, non-alcoholic steatohepatitis; oxLDL, oxidized low-density lipoprotein; PC, phosphorylcholine; T1LA, locomotor activity time; HE, hematoxylin and eosin; Cxxc10, C-X-C motif chemokine 10; Cc13, chemokine (C-C motif) ligand 3; Cd68, cluster of differentiation 68; Ctsd, cathepsin D; Acat2, acetyl-CoA acetyltransferase 2; Tnfl, tumor necrosis factor alpha; Cc12, chemokine (C-C motif) ligand 2; Mip2, macrophage inflammatory protein 2; BBB, blood brain barrier.
autoantibody titers against IgG and IgM antibodies to CuOx-LDL and PC-BSA have been described extensively (18).

**Lipid Measurements**
Total plasma cholesterol and triglyceride levels were measured (1489232, Chol CHOD-PAP, Roche, Almere, the Netherlands; 337-B, TG GPO-trinder, Sigma Aldrich, Zwijndrecht, the Netherlands). Measurements were done according to manufacturer's protocols on a Benchmark 550 Micro-plate Reader (170-6750XTU, Bio-Rad, Veenendaal, the Netherlands). TG were measured as described above. All analyses were performed according to manufacturers' instructions.

**Immunohistochemistry**
Frozen liver sections (7 μm) were fixed in acetone and blocked for endogenous peroxidase by incubation with 0.25% of 0.03% H₂O₂ for 5 min. Primary antibodies used were against neutrophils (rat anti-mouse Ly6C, clone NIMP-R14), hepatic macrophages (rat anti-mouse CD68, clone FA11), and infiltrated macrophages and neutrophils (rat anti-mouse Mac-1 [M1/70]). 3-Amino-9-ethylcarbazole (AEC) was applied as color substrate and hematoxylin for nuclear counterstain. Sections were enclosed with Faramount aqueous mounting medium. Pictures were taken with a Nikon digital camera DMX1200 and ACT-1 v2.63 software (Nikon Instruments Europe, Zwijndrecht, the Netherlands). For organ lipid analyses, 0.03% H₂O₂ and heat was considered as 120 s.

**Genotyping**
Genotypes of animals were determined by PCR analysis of tail DNA. Tails were clipped at postnatal day 6 and homogenized in DirectPCR-Tail (Peqlab, Erlangen, Germany) supplemented with a tenth part Proteinase K (Qiagen, Hilden, Germany). Three hours of incubation at 56°C and agitation at 1,000 rounds per minute on a Thermo Mixer were followed by 45 min of heating at 85°C to inactivate the proteinase. Samples were then spun at full speed in a benchtop centrifuge for 1 min. The PCR reactions were performed with 0.5 ml of the obtained extracts. Each lysate underwent two PCRs; Primers gcgaataggcgaggcat and cactactgtgtctctcatgtat identified the wild-type allele and primers gcgaataggcgaggcat and ttcgatgtctctctc identified the mutant allele. Both PCRs were carried out under similar cycling conditions.

**Pole Test**
The pole test was performed as previously described with minor modifications (37, 38). The mouse was placed head-upward on a small platform on top of a vertical rough-surfaced pole (diameter 10 mm; height 50 cm) and the time until the mouse descended to the floor (locomotor activity time: T_{LA}) was recorded with a maximum duration of 120 s. Even if the mouse descended part of the way and fell the rest of the way, the behavior was scored until it reached to the floor. When the mouse did not turn downward and instead dropped from the pole, T_{LA} was considered as 120 s because of maximal severity. The pole test was performed on 3 different days (day 18, 25, and 32), with 5 consecutive trials per mouse.
Accelerod (Accelerated Rotarod) Test
Balance and motor coordination of mice was evaluated using accelerated performance on day 21 and day 33 of the experiment. The accelerated system for mice was used under standard room conditions. The apparatus consisted of a base platform and a rotating rod with a grooved surface. Before accelerated testing, mice were trained at 2 separate days (day 17 and 19 of the experiment). On both training days, mice underwent 3 separate training moments (separated 2 h from each other) in which they endured 3 trials with a constant speed of 18 revolutions per minute for 120 s. When operated in the acceleration modus, the rotation increased from 4 to 40 revolutions per minute in 30 s steps within 5 min. The performance was measured as the latency to fall (s).

Statistical Analysis
Data were statistically analyzed by performing two-tailed non-paired t-test, two-way ANOVA followed by Tukey’s post-hoc correction and repeated measures two-way ANOVA followed by Tukey’s post-hoc correction using GraphPad Prism version 6 for Windows. Data were expressed as the mean and standard error of the mean. Data were considered significantly different compared to control-treated Npc1<sup>nih</sup> mice, except for the analyses of rotarod and pole test results, in which comparisons were made between different time points among the same study groups. (*p ≤ 0.05; **p < 0.01; ***p < 0.001; ****p < 0.0001).

RESULTS

Npc1<sup>nih</sup> Mice Recapitulate NPC1 Disease Features and Display Elevated Anti-oxLDL IgM Autoantibody Titers After Immunization With Heat-Inactivated Pneumococci
To assess the effects of the Npc1<sup>nih</sup> mutation, body, spleen and liver weight were compared between control-treated Npc1<sup>nih</sup> mice and age-matched wildtype mice. Whereas, total spleen weight was reduced in Npc1<sup>nih</sup> mice compared to wildtype mice, total liver weight was increased in Npc1<sup>nih</sup> mice (Supplementary Table S1). As expected, body weight of Npc1<sup>nih</sup> mice was reduced in comparison with age-matched wildtype mice (Supplementary Table S1), reflecting overall NPC1 disease burden. To determine whether anti-oxLDL IgM autoantibodies have a protective effect in NPC1, 2 week-old Npc1<sup>nih</sup> mice were immunized with heat-inactivated pneumococci, known to induce high anti-oxLDL IgM titers dominated by T15-idiotypic IgM (18, 31). While total body weight (Supplementary Figure S3A) and total liver weight did not differ (Supplementary Figure S3B), total spleen weight was decreased in immunized Npc1<sup>nih</sup> mice compared to control-treated counterparts (Supplementary Figure S3C). As expected, immunization resulted in a strong increase in plasma anti-oxLDL antibody levels in Npc1<sup>nih</sup> mice (Figures 1A,B). Only weak IgG responses were observed, which is in line with previous reports showing pneumococcal immunizations triggering an IgM-dominated thymus-independent type-2 response highly specific for phosphorylcholine (PC) (Figures 1C,D).

Delayed Motor Skill Degeneration and Improved Neuroinflammation and Cerebral Morphology in Immunized Npc1<sup>nih</sup> Mice
Motor skill degeneration is a common neurological feature of NPC1, due to the progressive loss of Purkinje cells. To determine the effects of the pneumococcal immunization on motor function of Npc1<sup>nih</sup> mice, pole and rotarod tests were performed throughout the study period. As expected, Npc1<sup>nih</sup> mice performance on both tests was consistently worse than their wildtype counterparts (Supplementary Table S1), confirming NPC1 disease burden on motor function. By the end of the study, control-treated Npc1<sup>nih</sup> mice took significantly longer time to descend the pole (Figure 2A), whereas locomotor activity time (T<sub>LA</sub>) of immunized Npc1<sup>nih</sup> mice remained stable over the entire experiment. Additionally, the motor function scores obtained for the pole test strongly correlate with the levels of plasma anti-oxLDL IgM autoantibodies, suggesting a link between the amount of circulating anti-oxLDL IgM autoantibodies and overall motor performance (Supplementary Figure S4).

While the performance of both control-treated and immunized Npc1<sup>nih</sup> mice on the rotarod test worsened significantly over time (Figure 2B), the observed performance decay was more prominent in the control-treated Npc1<sup>nih</sup> mice. These results indicate that motor function deterioration over time was decreased in immunized Npc1<sup>nih</sup> mice.

Next, we investigated whether pneumococcal immunization affects Purkinje cells in Npc1<sup>nih</sup> mice. In line with motor skill function results, the integrity of cerebella of control-treated Npc1<sup>nih</sup> was severely compromised, whereas immunized Npc1<sup>nih</sup> mice retained more of their cerebellar structure (Figures 2C,D and Supplementary Figure S5A). Furthermore, Purkinje cells of untreated Npc1<sup>nih</sup> mice displayed increased hematoxylin and eosin (HE) staining intensity, suggesting higher activation levels due to damage (Figure 2E, upper panel; Figure 2F and Supplementary Figure S5B). Overall, these results indicate that pneumococcal immunization delays cerebellar neurodegeneration in Npc1<sup>nih</sup> mice. In addition to severe cerebellar neurodegeneration, cortical immune cells were observed in control-treated Npc1<sup>nih</sup> mice, in contrast with immunized Npc1<sup>nih</sup> mice, suggesting higher levels of neuroinflammation in the control-treated group (Figure 2E, lower panel and Supplementary Figure S5B).

We further analyzed the effects of pneumococcal immunization on neuroinflammation by examining microglial cells using immunohistochemical staining for Iba-1 (Figure 2G). While no differences were observed in total number of microglia (Figure 2H), microglia of immunized Npc1<sup>nih</sup> mice exhibited larger cell bodies and shorter, less ramified processes, suggesting a change in microglia phenotype following pneumococcal immunization (Figure 2I).

Finally, we analyzed cerebral and cerebellar gene expression analysis of the inflammatory markers C-X-C motif chemokine 10 (Cxc10), chemokine (C-C motif) ligand 3 (Ccl3), and cluster of differentiation 68 (Cd68). Immunization of Npc1<sup>nih</sup> mice reduced expression of all inflammatory markers in the cerebrum, with the exception of Ccl3, in which a trend suggesting decreased expression was observed (Figure 2J).
In addition, while expression of Cxcl10 and Cd68 in the cerebellum tended to be decreased, expression of Ccl3 was reduced in the cerebellum of immunized Npc1<sup>nih</sup> mice (Figure 2K). Furthermore, gene expression of cathepsin D (Ctsd), a marker previously linked to NPC1 severity in mice (39, 40), and Npc2, which is known to bind to cholesterol in the lysosome, were reduced in the cerebrum of Npc1<sup>nih</sup> mice that received the immunization, indicating an improved neurological phenotype after immunization. Notably, cerebral and cerebellar expression of several of these markers correlated with the plasma anti-oxLDL IgM autoantibody levels (Supplementary Figure S4), underlining the link between the neurological phenotype and anti-oxLDL IgM autoantibody levels. Altogether, these results indicate beneficial effects of immunization with heat-inactivated pneumococci on the neurological phenotype of Npc1<sup>nih</sup> mice.

**Decreased Hepatic and Splenic Lipid Levels in Immunized Npc1<sup>nih</sup> Mice**

To determine whether immunizing Npc1<sup>nih</sup> mice with heat-inactivated pneumococci influences hepatic lipid levels, biochemical assessment of hepatic cholesterol and triglycerides was performed. Npc1<sup>nih</sup> mice showed an increase in plasma and liver cholesterol levels compared to age matched wildtype mice (Supplementary Table S1). Seven week-old Npc1<sup>nih</sup> mice that received the immunization demonstrated reduced levels of hepatic total cholesterol (Figure 3A) and triglycerides (Figure 3B) compared to control-treated Npc1<sup>nih</sup> mice, though the latter only showed a trend. In line, HE-staining of the liver confirmed the decrease of lipid levels in hepatocytes and the reduced foamy appearance of hepatic macrophages in immunized Npc1<sup>nih</sup> mice (Figures 3C,D). Relevantly, hepatic gene expression levels of acetyl-CoA acetyltransferase 2 (Acac2), the enzyme responsible for cholesterol esterification, were elevated in immunized Npc1<sup>nih</sup> mice, suggesting increased cholesterol esterification upon immunization (Figure 3E). In contrast, no differences were observed in plasma lipid levels between control-treated and immunized Npc1<sup>nih</sup> mice (Figures 3F,G). To obtain a more detailed view on hepatic lipid distribution, electron microscopy analysis was performed (Figure 3H). Though both control and immunized Npc1<sup>nih</sup> mice showed the NPC1 characteristics of hepatic lipid inclusions (blue circles) and vacuoles with electron-dense material (asterisk), immunized Npc1<sup>nih</sup> mice demonstrated a less foamy appearance of hepatic macrophages (arrow). In contrast with these observations, no differences were observed in lipid accumulation in the spleen of immunized Npc1<sup>nih</sup> mice and control-treated Npc1<sup>nih</sup> mice (Figures 3I,J). Overall, these results suggest improved hepatic lipid metabolism after increasing anti-oxLDL IgM autoantibody levels in Npc1<sup>nih</sup> mice.
Improved Hepatosplenic Phenotype in Immunized \(Npc1^{nih}\) Mice

To determine whether immunization of \(Npc1^{nih}\) mice affects hepatic inflammation, hepatic cryosections were stained for the inflammatory cell markers NIMP (neutrophils), CD68 (resident macrophages) and Mac-1 (infiltrated macrophages and neutrophils). The number of infiltrated neutrophils and macrophages in control-treated \(Npc1^{nih}\) mice was increased compared to wildtype mice, confirming increased hepatic inflammation in \(Npc1^{nih}\) mice (Supplementary Table S1). Following pneumococcal immunization, the number of neutrophils and resident macrophages were reduced \(Npc1^{nih}\) mice (Figures 4A,B,D). Although the number of infiltrated neutrophils and macrophages (Figure 4C) and HE-scoring of hepatic inflammation (Figure 3C and Supplementary Figure S6) did not reach statistical significance.
between study groups, a trend toward reduction of these parameters following immunization was observed. To confirm these histological findings, hepatic gene expression analysis was performed on the inflammatory markers tumor necrosis factor alpha (Tnfx), chemokine (C-C motif) ligand 2 (Ccl2), macrophage inflammatory protein 2 (Mip2). Tnfx and Ccl2 expression levels were significantly reduced in immunized Npc1<sup>nth</sup> mice compared to non-immunized Npc1<sup>nth</sup> mice (Figure 4E). The expression of Mip2 and Ctsd, a marker for disease severity, showed no difference between control-treated and immunized Npc1<sup>nth</sup> mice, although a trend suggesting reduced expression following immunization was observed.
(Figure 4E). As increased hepatic apoptosis is linked to inflammation and damage of the liver (41), hepatic apoptosis was also assessed. The amount of apoptotic cells, as quantified by HE-staining, was reduced upon immunization (Figure 4F), indicating an improvement of the NPC1 disease phenotype in the liver after pneumococcal immunization. Additionally, similar results were observed in the spleen, showing reduced expression of inflammatory markers, although in the case of Tnfα, only a trend was observed (Figure 5). Finally, hepsposplenic expression of most of these markers correlated with the plasma anti-oxLDL IgM autoantibody levels (Supplementary Figure S4), underlining the link between the systemic improvements and the anti-oxLDL IgM autoantibody levels. Altogether, these findings indicate an improved hepsposplenic phenotype in Npc1<sup>−/−</sup> mice that received the heat-inactivated pneumococci immunization, supporting its potential as treatment for NPC1 disease.

**DISCUSSION**

Due to severity of symptoms, delayed diagnosis and restricted therapeutical options, NPC1 disease patients suffer from a gradual impairment in quality of life and premature death. NPC1 disease commonly manifests through systemic symptoms, such as liver and spleen dysfunction, which precede neurological symptoms (epilepsy, movement disorder, dementia, among others). In this study, we show that heat-inactivated pneumococci immunization improves both systemic and neurological symptoms, including motor function, neurodegeneration, neuro- and systemic inflammation in a mouse model of NPC1 disease. In light of these promising results, we propose pneumococcal immunization as a novel therapeutic tool to ameliorate NPC1 disease severity, potentially in combination with treatments such as Miglustat and cyclodextrin (9, 42).

Although the role of oxLDL in neurodegenerative diseases has not been extensively investigated, oxLDL is involved in the pathogenesis of NASH and atherosclerosis, two diseases that share pathological mechanisms with NPC1 disease (19, 20, 43–46). Currently, there is no definite consensus on the benefits of targeting oxLDL by increasing anti-oxLDL antibodies in atherosclerosis, as some studies suggest that this approach increases inflammation and exacerbates disease severity (47–49). However, it should be noted that, in these studies, no
distinction was made between classes and idiotypes of anti-oxLDL antibodies. Although a study from Smook et al. (50) found no correlation between anti-oxLDL IgM autoantibody levels and advanced atherosclerotic lesion formation, this study could not establish whether anti-oxLDL IgM antibodies are anti or pro-atherogenic, and several other in vivo reports have found increased anti-oxLDL IgM antibody levels to be beneficial (51, 52). Thus, it is likely that the reported pathogenic effects of anti-oxLDL antibodies are due to the production of anti-oxLDL IgG, rather than IgM, antibodies. In atherosclerosis and NASH, pneumococcal immunization has been shown to ameliorate inflammation and disease severity (18, 20, 31), suggesting that this treatment may be beneficial to the systemic components of NPC1.

Although no effects were observed on splenic lipid accumulation following pneumococcal immunization, expression of several inflammatory genes was improved in the spleen of immunized Npc1<sup>inh</sup> mice. Of note, in this study, we observed reduced spleen weight in control-treated Npc1<sup>inh</sup> mice compared to wildtype mice instead of characteristic splenomegaly of NPC1 disease, indicating that this model does not recapitulate the spleen NPC1 disease phenotype. In contrast to spleen observations, liver weight and cholesterol accumulation as well as hepatic inflammation were increased in control-treated Npc1<sup>inh</sup> mice compared to wildtype counterparts. Following pneumococcal immunization, liver apoptosis, hepatosplenic inflammation and hepatic cholesterol accumulation were decreased in immunized Npc1<sup>inh</sup> mice, although the latter effects were of low magnitude. In addition to targeting oxLDL, immunization with heat-inactivated pneumococci is also known to improve clearance of apoptotic cells, due to molecular mimicry between apoptotic cells and S. pneumoniae (31). Indeed, after immunization, Npc1<sup>inh</sup> mice displayed lower levels of apoptotic liver cells. Therefore, the beneficial effects of heat-inactivated pneumococci immunization in our study can partly derive from increased clearance of apoptotic cells.

As expected, control-treated Npc1<sup>inh</sup> mice showed motor function deficits as assessed by the pole and rotarod tests, confirming neurological impairments in these mice compared to wildtype mice. In this study, unlike control-treated Npc1<sup>inh</sup> mice, the performance of immunized Npc1<sup>inh</sup> mice on the pole test remained unchanged over time. Additionally, immunized Npc1<sup>inh</sup> mice displayed less prominent decay on rotarod test performance compared to their control-treated counterparts. It should be noted that, unlike the beam walking or the catwalk test, several neuronal circuits are involved in pole and rotarod test performance (53). As such, we are unable to pinpoint the specific skills that were improved by pneumococcal immunization. Nonetheless, our results indicate an overall improvement in motor function decay following pneumococcal immunization in Npc1<sup>inh</sup> mice, in line with observed reduction in neuroinflammation and cerebellar damage.

The mechanisms leading to improved neurological features in Npc1<sup>inh</sup> mice following pneumococcal immunization are unclear. IgM antibodies are large molecules and are thus usually precluded from the nervous system due to the blood brain barrier (BBB). As such, whether peripheral immunization strategies can be effective in the nervous system is a controversial matter. Nonetheless, peripheral immunization in Alzheimer’s disease and amyotrophic lateral sclerosis has been shown to elicit beneficial effects in the nervous system with as little as 0.1% antibody passage through the BBB (54, 55). Furthermore, it has been proposed that antibodies in the nervous system facilitate the corresponding ligand efflux to the periphery, thus contributing to its clearance (55). As such, it is possible that the neurological improvements observed in this study derive from anti-oxLDL IgM autoantibody-mediated oxLDL clearance to the periphery and/or prevention of oxLDL uptake by microglia scavenger receptors, as has been proposed for macrophages (56, 57). On the other hand, live S. pneumoniae can cross the BBB due to certain membrane-surface proteins (58) that may be retained after heat-inactivating the bacteria. Although more thorough analyses are required to derive conclusions regarding microglia activation state, following pneumococcal immunization we observed a shift in microglia morphology that is commonly associated with a phenotypical change in these cells (59). While we are unable to pinpoint whether this is a response to interaction of microglia with anti-oxLDL IgM autoantibodies, complement activation or heat-inactivated pneumococci recognition, the latter option is unlikely, as previous reports suggest that heat-inactivated S. pneumoniae are non-immunogenic in the nervous system (60). Of note, in vitro and in vivo studies have shown that endothelial cells in the BBB are susceptible to oxLDL-induced cytotoxicity (61–63). Therefore, it is possible that high levels of plasma oxidized cholesterol products and oxLDL in NPC1 disease increase BBB permeability and exacerbate neurological symptoms, a concept that has previously been proposed in Alzheimer’s disease (63). In support of these observations, the observed immune cells in the cortex of untreated Npc1<sup>inh</sup> mice may result from a compromised BBB integrity. As such, improved neurologic symptoms following immunization in NPC1 disease could further derive from an improved BBB phenotype and function.

Persistent systemic- and neuroinflammation are well-described characteristics of NPC1 disease. While, under physiological conditions, inflammatory processes encourage the clearance of toxic compounds and the repair of injured...
tissues, the inability to overcome a pathological stimulus causes the persistent inflammatory response to become detrimental. Therefore, reducing inflammation and its associated pathological burden might be a promising approach to reduce NPC1 disease severity. In line with this view, administering non-steroidal anti-inflammatory drugs (NSAID) has been shown to improve motor function, body weight and even survival in a mouse model for NPC1 disease (64). Based on these findings, one can speculate on the direct role of inflammation in NPC1 disease severity and progression, despite it not being the primary cause of the disease. Similarly, though also initially not acknowledged as an essential disease component, inflammation is now accepted as a key component in disorders such as atherosclerosis (65), and Alzheimer’s disease (66). Therefore, the role of inflammation in NPC1 disease and its usefulness as a therapeutic target should be further investigated.

Currently, therapeutic interventions for NPC1 disease focus on symptom management, and no curative treatments are available (67). As several mechanisms downstream of lysosomal lipid accumulation contribute to NPC1 disease pathology, interventions targeting different key features of NPC1 disease are likely to have increased benefits compared to mono-therapeutic strategies. In line with this rationale, in vitro and in vivo studies have analyzed the effects of combining therapies to improve cellular lipid accumulation, oxidative stress, inflammation and intracellular calcium homeostasis (64, 68). Overall, such studies found that combined therapies outperform the use of single compounds, highlighting the benefits of tackling different pathological mechanisms in NPC1 disease. For instance, the effects of improved cellular lipid accumulation, considered to be at the root of NPC1 disease pathology, are amplified when combined with anti-inflammatory and antioxidant compounds (68). As such, the investigation of pneumococcal immunization in combination with direct lysosomal lipid mobilizers (i.e., cyclodextrin) may be an attractive future approach for NPC1 disease patients.

Despite the promising features of pneumococcal vaccination, some points should be addressed before it can be used as a treatment for NPC1 disease. Although the impact of spleen damage on the immune system of NPC1 disease patients has yet to be analyzed, it is likely that the latter is compromized to some extent, which may in turn decrease the efficacy of immunotherapy. Furthermore, it was not yet assessed whether pneumococcal immunization is efficient in the context of NPC1 disease not just as a treatment but also as a preventive tool. In addition, in this study, Npc1<sup>nth</sup> mice received two booster pneumococci immunizations, whereas pneumococcal vaccination in humans is usually performed once every several years, which may not be enough for therapeutically relevant oxLDL clearance (69). Nevertheless, it is worth taking into consideration that one of the most common manifestations of NPC1 is dysphagia, whose complications range from malnutrition to lung infections, mainly, bronchopneumonia (70–73). The fact that bronchopneumonia is a major cause of death in NPC1 disease patients is therefore another compelling argument for using pneumococcal immunization in these patients. The use of pneumococcal vaccinations against pneumonia is widespread (74–78). Furthermore, due to its long practice in the clinic, many optimizations of the vaccine have taken place, guaranteeing its safety even in vulnerable individuals such as pregnant women, young children, and the elderly (75–77). It should be noted that different S. pneumoniae strains as well as other bacteria, possess the phosphorylcholine epitope that triggers the production of anti-oxLDL IgM autoantibodies by means of molecular mimicry (31, 79). Nevertheless, it was so far not investigated whether immunization using these bacteria also elicits beneficial effects on lipid metabolism and inflammation. Furthermore, in this study, some of the phenotypical improvements, although statistically significant, were of low magnitude (i.e., hepatic cholesterol accumulation). Whether these effects can be enhanced by combining pneumococcal immunization with other NPC1 disease treatments or by using different immunogens should be explored in the future. Overall, considering the promising results in this study, further research is warranted to fully assess the most efficient way to modulate anti-oxLDL immune responses via pneumococcal vaccination in NPC1 disease patients.

**FINAL REMARKS**

For the first time, we demonstrate that increasing anti-oxLDL IgM autoantibodies ameliorates motor function decay, neuro- and hepatic inflammation as well as hepatic cholesterol metabolism in NPC1 disease. In light of the present findings, we propose pneumococcal immunization, potentially in combination with other available treatments, as a novel therapeutic tool for NPC1 disease.

**AUTHOR CONTRIBUTIONS**

TJo, IM, CB, JP, RS-S did the conception and design of the study. TJo, IM, THe, HS, MG were involved with acquisition of data. TJo, IM, THe, DC, JP, RS-S performed the (statistical) analysis and interpretation of data. TJo, IM, DC, CB, JP, RS-S drafted the manuscript. TJo, IM, YO, MW, and RS-S revised the manuscript. All authors were involved in revising the paper critically and gave final approval of the version to be submitted.

**FUNDING**

This research was supported by the Netherlands Organisation for Scientific Research (NWO) (Vidi grant number: 016.126.327; ASPASIA grant number: 015.008.043) and CVON IN-CONTROL (CVON 2012-03). MW is supported by Netherlands Organization of Scientific Research (NWO) VIDI-grant 917.15.350 and a Rosalind Franklin Fellowship from the University Medical Center Groningen.

**ACKNOWLEDGMENTS**

We would like to thank Prof. Dr. Lieberman, from University of Michigan Medical, for kindly gifting the Npc1<sup>nth</sup> mice used in this study. We further like to thank Laure Verstraeten and Ilona Cuijpers for their excellent technical support.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fimmu.2018.03089/full#supplementary-material

Supplementary Figure S1 | Overview of experimental set-up.

Supplementary Figure S2 | Representative pictures of microglia phenotype scoring (400x).

Supplementary Figure S3 | General parameters. (A) Weight of Npc1<sup>nth</sup> mice throughout study. (B,C) Absolute liver and spleen weight.

Supplementary Figure S4 | Correlations between IgM antibody levels and gene expression levels of markers in the brain, liver, and spleen.

Supplementary Figure S5 | Representative pictures and scoring of calbindin staining of Purkinje cells in cerebellum (400x). (A) General histology of the brain by HE staining; Purkinje cells (top panel, 400x) and immune cell (bottom left panel, 200x). (B).

Supplementary Figure S6 | Liver HE inflammation scoring.

Supplementary Table S1 | Parameters of 7 week-old wildtype and control-treated Npc1<sup>nth</sup> mice.
