Ex situ dual hypothermic oxygenated machine perfusion (DHOPE) and normothermic machine perfusion (NMP) of donor livers may have a complementary effect when applied sequentially. While DHOPE resuscitates the mitochondria and increases hepatic adenosine triphosphate (ATP) content, NMP enables hepatobiliary viability assessment prior to transplantation. In contrast to DHOPE, NMP requires a perfusion solution with an oxygen carrier, for which red blood cells (RBC) have been used in most series. RBC, however, have limitations and cannot be used cold. We, therefore, established a protocol of sequential DHOPE, controlled oxygenated rewarming (COR), and NMP using a new hemoglobin-based oxygen carrier (HBOC)-based perfusion fluid (DHOPE-COR-NMP trial, NTR5972). Seven livers from donation after circulatory death (DCD) donors, which were initially declined for transplantation nationwide, underwent DHOPE-COR-NMP. Livers were considered transplantable if perfusate pH and lactate normalized, bile production was ≥10 mL and biliary pH > 7.45 within 150 minutes of NMP. Based on these criteria five livers were transplanted. The primary endpoint, 3-month graft survival, was a 100%. In conclusion, sequential DHOPE-COR-NMP using an HBOC-based perfusion fluid offers a novel method of liver machine perfusion for combined resuscitation and viability testing of suboptimal livers prior to transplantation.

1 | INTRODUCTION

Ex situ machine perfusion is increasingly investigated as a tool to increase the number of donor livers for transplantation and to reduce posttransplant complications. Machine perfusion, was recently introduced in clinical practice using two different temperature protocols: hypothermic (4-12°C) or normothermic (37°C) machine perfusion. (Dual) hypothermic oxygenated perfusion ([D]HOPE) can be applied to resuscitate the mitochondria and increase hepatic adenosine triphosphate (ATP) content, resulting in less cell injury, including less cholangiocyte injury. Normothermic machine perfusion (NMP) allows for ex situ functional testing of (extended criteria) donor livers prior to transplantation and suboptimal donor livers have been successfully transplanted after NMP. (D)HOPE and NMP may therefore have a complementary effect when applied sequentially.

In preclinical studies using human donor livers, it was previously shown that a short period of DHOPe prior to NMP results in increased ATP concentrations, less hepatobiliary injury and improved function during the NMP phase, compared to direct end-ischemic NMP.

Different perfusion solutions have been used for (D)HOPE and NMP. A perfusion fluid based on human red blood cells (RBC) is frequently used for NMP. The use of RBC, however, has several drawbacks. Firstly, RBC are a relatively scarce human blood product. Secondly, RBC may induce an immune reaction or cause an infection. Lastly, RBC cannot be used during (D)HOPE due to increased stiffness of the erythrocyte lipid membranes and hemolysis at low temperatures. These drawbacks press the need for an alternative oxygen carrier, especially when hypothermic and normothermic machine perfusion are combined. Hemoglobin-based oxygen carriers (HBOC) are a suitable alternative for the use of RBC in ex situ liver machine perfusion. The bovine derived HBOC-201 (Hemopure) has previously been used successfully in experimental and preclinical studies of liver machine perfusion.

Based on the presumed complementary effect of (D)HOPE and NMP we have combined these two techniques in a clinical machine perfusion protocol using an HBOC-201-based solution. The use of this perfusion solution eliminates the need to change the perfusion fluid during different temperature phases. Donor livers that were initially declined for transplantation nationwide were subjected to a combined protocol of DHOPe, controlled oxygenated rewarming (COR), and subsequent viability testing during NMP (DHOPe-COR-NMP Trial). This report describes the first transplantations of initially nation-wide declined livers that underwent ex situ machine perfusion with the HBOC-201-based perfusion fluid.

2 | MATERIALS AND METHODS

2.1 | Study protocol

Between August 2017 and April 2018, 20 livers were offered for inclusion in the DHOPe-COR-NMP study. All livers were declined for regular transplantation by the three liver transplant centers in the Netherlands. Thirteen livers were secondarily declined because of logistical reasons, long agonal phase (in case of donation after circulatory death), or macroscopic fibrosis/cirrhosis (Figure 1 and Figure S1). Seven livers were accepted to undergo DHOPe-COR-NMP. All seven livers were initially declined for transplantation because of a combination of risk factors, as described in Table 1. The median donor risk index was 2.82 (IQR 2.52-2.97), reflecting the suboptimal quality of these livers.

The study protocol was approved by the medical ethical review committee of our center (METc2016.281) and published in the national registry of clinical trials (www.trialregister.nl; NTR5972). The primary outcome parameter was 3-month graft survival. All recipients gave written informed consent.

2.2 | Procurement of donor livers

All donor livers were procured in a standard manner by a dedicated procurement team. After withdrawal of mechanical support,
circulatory death was awaited, followed by a mandatory 5 minutes “no touch” period before procurement surgery was started. Cold in situ flush was performed with UW cold storage solution with the addition of 50 000 IU of heparin. After procurement, the livers were transported to our center using static cold storage. Upon arrival, the livers were prepared for machine perfusion, as described previously.

### 2.3 Machine perfusion settings

A combined machine perfusion protocol of 1 hour of DHOPE (resuscitation phase), 1 hour of COR, and subsequent NMP (viability testing phase) was established (Figure 2). For machine perfusion at different temperatures the Liver Assist (Organ Assist, Groningen, the Netherlands) perfusion device was used. DHOPE was performed at 10°C. During COR the temperature was gradually increased about 1°C per 2 minutes, to 37°C at the start of NMP. Portal vein and hepatic artery pressures were set at 5 and 11 mm Hg during DHOPE, and gradually increased during COR to 11 and 70 mm Hg at the start of NMP, respectively.

During DHOPE, the perfusion fluid was oxygenated with 1 L/min 100% O₂, resulting in a perfusate pO₂ > 80 kPa, as described previously. During NMP an air/oxygen mixture was used aimed to reach an arterial perfusate pO₂ of 10.0-13.3 kPa and a venous oxygen saturation of 55% to 75%. To obtain these targets, FiO₂ was varied between 21% and 40%.

Arterial perfusate samples were collected every half hour and analyzed using the ABL 90 Flex analyzer (Radiometer, Brønshøj, Denmark). In addition, venous perfusate samples were collected and analyzed every hour, to determine oxygen consumption. Oxygen consumption was calculated based on the difference between arterial and venous oxygen content. The following equation was used, (\(\frac{[\text{ApO}_2 - \text{VpO}_2] \times K}{760} \times \text{total flow} + \frac{[\text{AsO}_2 - \text{VsO}_2] \times \text{Hb} \times c \times 0.0001}{18}\times \text{total flow}) / \text{Liver weight} \times 100\). Where pO₂ was in mm Hg, SO₂ in %, Hb in g/dL, total flow (sum of arterial and portal flow) in mL/min and liver weight in g. K was a constant (0.0225) and c the oxygen binding capacity of HBOC (1.26).

Bile was collected from COR-NMP onwards and its quantity measured. Additionally, every half hour bile was collected under mineral oil to determine biliary pH and HCO₃⁻, as described previously. Mineral oil prevented exposure of bile to ambient air, thus preventing the exchange of CO₂ molecules, which influences biliary pH via HCO₃⁻.

### 2.4 Perfusion fluid

To facilitate perfusion at different temperatures, an acellular perfusion solution based on a bovine-derived HBOC (HBOC-201, HBO Therapeutics, Souderton, PA) was used. In addition to HBOC-201, the perfusion fluid contained gelofusine, albumin, metronidazole,cefazolin, nutrients, glutathione, insulin, heparin, and NaHCO₃. Details of the perfusion solution composition are provided in Table S1. As of liver #6, taurocholate was added to the perfusion fluid (50 mg at baseline), followed by a continuous infusion of 7.7 mg/h during the NMP phase. Taurocholate was produced according to GMP by our hospital pharmacy.

### 2.5 Viability testing—assessment of hepatobiliary function

Liver viability and function were assessed during the NMP phase using predefined viability criteria, including sufficient bile production.

with a biliary pH of >7.45, and normalization of perfusate pH and lactate (Table 2). The liver was considered acceptable for transplantation, if all criteria were met within the first 150 min of NMP. If the liver did not meet the predefined viability criteria, machine perfusion was terminated. If the liver did meet the predefined viability criteria, machine perfusion was continued and the recipient was brought to the operating room. When the hepatectomy of the native liver was almost complete, machine perfusion was terminated and the donor liver flushed out with 2 L of cold UW cold storage solution to remove the HBOC-based machine perfusion fluid. As routinely performed in our center, the first 400 mL of venous blood from the liver was drained and discarded to avoid spill of UW Cold Storage Solution into the recipient circulation.

3 | RESULTS

3.1 | Machine perfusion characteristics

Five of the seven livers (liver #1, and #4-#7) that underwent DHOPE-COR-NMP were identified as transplantable based on functional assessment during NMP (Table 3). Median cold ischemia time of all livers was 289 minutes (IQR 256-306 minutes). Machine perfusion times per liver are provided in Table 4. Median total duration of machine perfusion was shorter for the non-transplanted livers due to termination of machine perfusion after these livers did not meet all predefined viability criteria within 150 min of NMP.

Both portal vein and hepatic artery flow remained low during DHOPE and increased during COR. At 150 minutes of NMP, median portal vein flow was 1680 mL/min (IQR 1460-1740 mL/min) (Figure 3A). Overall, resistance in the portal vein decreased towards NMP, but remained relatively high in liver #3 (Figure 3B). At 150 minutes of NMP, median hepatic artery flow was 547 mL/min (IQR 240-737 mL/min). Furthermore, hepatic artery flow was variable between the livers (Figure 3C). Resistance in the hepatic artery, generally remained <0.2 mm Hg*min/L/g, except for resistance in liver #7 (Figure 3D). During COR, total flow increased as well, to a median of 2512 mL/min (IQR 2133-2570 mL/min) at 150 minutes of NMP (Figure 3E).

3.2 | Hepatobiliary function and damage during machine perfusion

Perfusate pH normalized within 150 minutes of NMP of liver #1, #2, and #4 to #7, but not in liver #3, despite the addition of 25 mL 8.4% NaHCO₃ (Figure 4A). Perfusate lactate normalized within 150 minutes of NMP in all livers, except for liver #3 (Figure 4B). Furthermore, all livers produced sufficient amounts of bile. Bile production of liver #6 appeared lower, however, this was caused by a cannulation problem of the bile duct (Figure 4C). Alanine aminotransferase (ALT) concentrations in perfusate of the transplanted livers were <2000 U/L. In the two non-transplanted livers ALT concentrations were >2000 U/L, with a peak ALT concentration of 8460 U/L in liver #3 (Figure 4D). Livers #1 and #4 to #7 produced bile with a
FIGURE 3 Flows and resistance during machine perfusion. A, Porta l vein (PV) flows were low during DHOPE. After 150 min of NMP, median portal vein flow was 1680 mL/min (IQR 1460-1740 mL/min). B, Resistance in the portal vein was low, except for liver #3. C, Hepatic artery (HA) flows were low during DHOPE and COR. During NMP hepatic artery flows varied between 100 and 900 mL/min. At 150 min of NMP, median hepatic artery flow was 547 mL/min (IQR 240-737 mL/min). D, Resistance in the hepatic artery was <0.2 mm Hg*min/L/g, except for liver #7. E, Total flow increased to a median of 2512 mL (IQR 2133-2570 mL) at 150 minutes of NMP. The red lines represent the non-transplanted livers and the green lines represent the transplanted livers. NMP, normothermic machine perfusion.

pH > 7.45, whereas livers #2 and #3 did not (Figure 4E). Bile duct biopsies of these two livers revealed signs of substantial histological injury (Figure S2).

Median oxygen consumption was 0.14 mL O₂/min/100 g liver weight during DHOPE and increased during COR to a median peak value of 2.77 mL O₂/min/100 g liver weight during NMP.

3.3  Pre- and postoperative outcomes

Median follow up after transplantation was 197 days (IQR 152-307 days). Laboratory values of the recipients are shown in Figure 6. Serum ALT levels rapidly decreased during the first week after transplantation and values were (nearly) normal at 30 and 90 days after transplantation. The recipients of liver #1 and #7 had remarkably low peak serum ALT concentrations of 201 and 337 U/L, respectively (Figure 5A). Serum total bilirubin levels rapidly decreased during the first postoperative days in all recipients. However, a temporary peak in serum bilirubin was noted at the end of the first week in recipients of liver #4 and #6 (Figure 5B). None of the transplanted livers classified for early allograft dysfunction.

Thus far we have observed a 100% patient and graft survival. None of the recipients has developed clinically evident non-anastomotic strictures of the biliary tree during the median follow-up of 197 days (6.5 months).

4  DISCUSSION

The clinical series described in this report provides two novel findings that are relevant for the further development of machine perfusion technology in organ transplantation. First, we have successfully used a combination of hypothermic and normothermic machine perfusion to resuscitate and select initially declined suboptimal livers for transplantation. The 100% graft survival at 3 months, which was the primary end point, indicated the safety and feasibility of the procedure. Secondly, we have shown that an HBOC-based machine perfusion solution can be safely used in clinical liver transplantation.

Several groups have described the successful use of NMP to select suboptimal and initially declined donor livers. Although the optimal parameters for viability assessment are still under debate, most groups have been using a combination of bile production, perfusate lactate levels, and pH as markers of hepatocellular function. We have previously suggested to use biliary pH and bicarbonate as markers of biliary epithelial (cholangiocellular) viability. Biliary epithelium actively modifies bile composition by the secretion of bicarbonate, resulting in an alkalotic biliary environment. This alkalotic environment protects biliary epithelial cells against the detergent effects of hydrophobic bile salts, a phenomenon known as the “bicarbonate umbrella.” In a clinical series of liver NMP, Watson et al. have recently confirmed the potential usefulness of biliary pH as marker of biliary viability.

Although, favorable outcomes after NMP regarding graft and patient survival have been reported, it has not yet been demonstrated that NMP protects the cholangiocyte compartment. DHOPE in DCD liver grafts has, on the other hand, been described to reduce histological signs of biliary ischemia-reperfusion injury and the incidence of posttransplant cholangiopathy. Furthermore, DHOPE has been shown to reduce ischemia reperfusion injury via resuscitation of the mitochondria and the increase in hepatic ATP content, thereby also protecting the hepatocytes.

Thus far, we have observed a 100% patient and graft survival. None of the recipients has developed clinically evident non-anastomotic strictures of the biliary tree during the median follow-up of 197 days (6.5 months).

We applied sequential DHOPE and NMP linked by a controlled rewarming phase, as sudden temperature shifts may contribute to celluar injury. A previous clinical study has indicated that a short period of COR prior to implantation of donor livers results in less hepatocellular injury, compared to direct implantation of a cold stored donor liver, as evidenced by lower postoperative peak transaminases and a higher graft survival rate at 6 months after transplantation. Based on the relative small number of livers included in the current study and the absence of a control group, we cannot draw conclusions on the value of the COR phase. Previous preclinical studies have shown that (D)HOPE and NMP can also be combined without a COR phase.
For the application of this combined machine perfusion protocol we have developed a perfusion fluid that can be used at various temperatures and eliminates the use of a third party human blood product. While during hypothermic machine perfusion, oxygen can be dissolved in the perfusion solution, during NMP an oxygen carrier is necessary. Perfusion solutions based on RBC, which are mostly used for NMP, cannot be used at low temperatures due to increasing lipid membrane stiffness and the risk of hemolysis. In contrast to RBC, HBOC can be used at low temperatures. In addition, HBOC-201, used in this study, has a lower oxygen affinity than human Hb in erythrocytes and thus gives off the oxygen more easily. In the cold, the affinity of HBOC-201 for oxygen increases, similar to that of human Hb in erythrocytes, but is still less.

HBOC-201 has previously been used in experimental and preclinical studies on ex-situ liver machine perfusion, but not in clinical practice. In a study with discarded human livers, NMP with an HBOC-201-based perfusion fluid resulted in similar outcome compared to NMP with RBC, indicating HBOC-201 as a suitable alternative for RBC. Our group reported higher ATP concentration, and cumulative bile production in discarded human livers undergoing NMP with an HBOC-201-based solution, compared to perfusion with an RBC-based perfusion fluid. Altogether these preclinical studies and the currently presented first, clinical application indicate that HBOC-201 can be used as a substitute for RBC in fluids for machine perfusion of donor organs.

A limitation of this series is a lack of a control group. However, livers of suboptimal quality with a perceived high risk of primary nonfunction or early allograft dysfunction were included in the current study, making it unethical, in our opinion, to transplant these livers without resuscitation and functional assessment. Furthermore, this study cannot discriminate between the beneficial effects of DHOPE, COR, and NMP separately. Finally, extrahepatic bile duct biopsies of the two livers that were secondary declined for transplantation, based on their failure to produce bile with a pH > 7.45 during NMP, were taken. Yet, biopsies of higher level bile ducts were not taken. Although we have previously shown that the degree of histological injury of the extrahepatic bile duct of a donor liver after cold storage is representative for the degree of injury of the proximal biliary tree, including larger intrahepatic ducts, we do not formally know whether this is also true after NMP.

A potential limitation of HBOC is its susceptibility to a conversion into methemoglobin, especially in the venous phase with low oxygen saturation. In contrast to erythrocytes, HBOC do not contain NADH-dependent enzyme methemoglobin reductase, which is responsible for converting methemoglobin back to hemoglobin. We have noted a gradual increase in methemoglobin during NMP, but not during DHOPE when the perfusion fluid was oxygenated with an FiO₂ of 100% (Figure S3). In a separate experiment, we have noted that the percentage of methemoglobin can be corrected or slowed down by the addition of extra HBOC-201, glutathione, or vitamin C to the perfusion fluid (Figure S3). However, we do not prefer the use of vitamin C due to its effects on the pH and osmolality of the perfusion fluid.

In conclusion, this first clinical experience demonstrates the feasibility of combined hypo- and normothermic machine perfusion after traditional static cold storage of suboptimal liver grafts. The combination of oxygenated hypothermic and normothermic perfusion protects livers against ischemia-reperfusion injury and enables hepatobiliary viability assessment prior to transplantation. The use of a novel HBOC-201-based perfusion fluid eliminated the need to

change perfusion fluid during various temperature phases and appeared to be a safe alternative for RBC as oxygen carrier in ex situ donor organ machine perfusion. This new protocol of ex situ machine perfusion provides a tool to safely expand the pool of organs for liver transplantation.

ACKNOWLEDGMENTS

We are grateful to Zafiris Zafirelis (HBOC Therapeutics) for providing HBOC-201 free of charge and for his advice on the use of this product. Moreover, we want to thank our organ perfusionists (Rinse Ubbink, Maureen Werner, Gert-Jan Pelgrim and Leonie Venema) for their help during the machine perfusion procedures. Funding was obtained by the Dutch Ministry of Health, Welfare and Sport and the Jan Kornelis de Cock Foundation, Groningen, the Netherlands. HBOC-201 was provided free of charge by HBO2 Therapeutics.

DISCLOSURE

The authors of this manuscript have no conflicts of interest to disclose as described by the American Journal of Transplantation.
