Key question

Does the effect of coronary artery bypass grafting on quality of life vary with age?

Key finding

One out of 3 patients aged ≥80 years experiences a decline in mental quality of life after coronary bypass.

Take-home message

Considerations before coronary bypass surgery should include quality of life prognosis.

†Presented at the 32nd Annual Meeting of the European Association for Cardio-Thoracic Surgery, Milan, Italy, 18–20 October 2018.

Abstract

OBJECTIVES: In this study, our aim was to explore how coronary artery bypass grafting affects quality of life, and how this varies with age, particularly with patients at risk of deterioration.

METHODS: In a retrospective, multicentre cohort study, patients with isolated coronary artery bypass grafting and electively operated between January 2011 and January 2015 with pre- and postoperative quality-of-life data were included. Patients were classified into 3 age groups: <65, 65–79 and ≥80 years. Quality of life was measured up to 1-year follow-up using the Short Form-12 or the Short Form-36 health survey. A multivariable, linear regression analysis, with an adjustment for confounders, was used to evaluate the association between age and quality of life.

RESULTS: A total of 2606 patients were included in this study. Upon one-year of follow-up, the mean physical health of patients increased from 54 at baseline to 68, and mental health increased from 60 to 67. We observed decreased mental health in 20% of patients aged <65 years, 20% of patients aged 65–79 years and 29% of patients aged ≥80 years (P = 0.039). In this study, age was not associated with a lower physical or mental component score (P = 0.054 and P = 0.13, respectively). Independent risk factors for a decrease in quality of life consist of a better physical and mental score at baseline (P < 0.001) and a reduced left ventricular function (P < 0.001).

CONCLUSIONS: Most patients experience a relevant increase in physical and mental quality of life, but a proportion of patients aged ≥80 years undergo significant deterioration in mental health.

Keywords: Cardiac surgery • Coronary artery bypass grafting • Quality of life

INTRODUCTION

During the past decades, in Western countries, increasing life expectancy has resulted in a greater number of elderly people. Between 2011 and 2040, the Dutch population of 75 years and older is expected to double from 1.2 million to 2.6 million [1, 2]. As a result, during the next 30 years the number of patients with heart disease will increase by ~55% [2], as will the number of older patients who might benefit from cardiac surgery. Meanwhile, continued advances in operative techniques, myocardial protection and perioperative care have led to a steady decline in operative mortality [3], thus further augmenting the number of elderly patients with a history of cardiac surgery.

Before making an informed decision as to whether to operate, one must weigh the potential advantages and disadvantages for each individual patient. The main reason to offer cardiac surgery is to improve survival and quality of life (QoL) [4]. The assessment of outcome measures has shifted from a physician’s perspective towards the patient’s perspective, and QoL is of critical importance for decision-making [5]. So far, findings on benefits in terms of QoL have been contradictory. Some studies report improvements in QoL [6, 7], whereas other studies allude to deterioration [8, 9]. Two review articles [9, 10] on QoL after coronary artery bypass grafting (CABG) have argued the need for more well-designed studies with a large number of patients, including preoperative and long-term postoperative quality-of-life data and information on patients lost to follow-up, to establish the generalizability of the results.

In this multicentre study, we evaluate in a large cohort of patients the influence of CABG on 1-year QoL and its variation with age. We also explore whether it is possible to identify characteristics of subgroups marked by deterioration in QoL.

MATERIALS AND METHODS

We conducted an observational, retrospective multicentre cohort study. The study was approved by the institutional review board of the Catharina Hospital Eindhoven (no. 2014-20), and conducted in agreement with the principles of the Helsinki declaration. The study is reported according to the REPorting of studies Conducted using Observational Routinely collected health Data (RECORD) guidelines [11] (Supplementary Material Section S1 checklist).

Eligibility criteria

We included all adult patients who had undergone elective CABG and were operated between 1 January 2011 and 1 January 2015, and for whom preoperative and 1-year follow-up QoL data were available. Patients were operated in one of the 3 participating centres in the Netherlands: Isala Zwolle, Catharina Hospital Eindhoven or St. Antonius Hospital, Nieuwegein. We classified patients into 3 age groups: younger than 65 years, between 65 and 79 years and 80 years or older. We retrieved baseline demographic and clinical characteristics from the Netherlands Heart Registry (formerly Meetbaar Beter), a nationwide initiative of cardiac surgeons and cardiologists to improve the quality and transparency of care for patients with heart disease. All participating centres systematically collected patient-oriented and clinically relevant outcome measures [12]. We obtained mortality data from the regional municipal administration registration.

Baseline characteristics

Baseline demographic data included age, sex, body mass index (BMI), logistic European System for Cardiac Operative Risk Evaluation (log EuroSCORE I) and perioperative data, including the use of cardiopulmonary bypass and the number of grafts. We also collected data on previous cardiac surgery and comorbidities such as diabetes mellitus (oral therapy or insulin-dependent diabetes) [13], pulmonary disease (prolonged use of steroids or other lung medication) [14], arterial vascular disease (peripheral or abdominal vascular pathology or operation due to arterial vascular disease) [14], renal disease (a reduced renal function prior to surgery with an estimated glomerular filtration rate <60 ml/min/1.73 m²) [15] and ventricular function (left ventricular ejection fraction: good >50%, moderate 30–50% or poor <30%) [16]. The log EuroSCORE I is a widely used risk stratification system, which estimates the mortality risk for individual adult cardiac surgery patients [17].
Outcome measures

The primary outcome was QoL, which was assessed using the Short Form Health Survey-36 (SF-36; version 2) or the Short Form Health Survey-12 (SF-12; version 2). The SF-36 is a validated and widely used questionnaire for the assessment of QoL. The questionnaire consists of 8 domains: vitality, physical functioning, bodily pain, general health perceptions, physical role functioning, emotional role functioning, social role functioning and mental health [18]. The SF-12 is a shortened version of the SF-36 questionnaire, developed to limit the survey length [19]. Two summarized scores can be calculated from both instruments: a physical component summary (PCS) and a mental component summary (MCS). A higher score indicates a better QoL; a score of zero is equivalent to maximum disability and a score of 100 is equivalent to no disability [18]. The Isala and Catharina Hospitals used the SF-36 questionnaire, and the St. Antonius Hospital used the SF-12 questionnaire. Because the same domain and summary scores are calculated with a standard syntax file, and because in patients with coronary disease the sensitivity and responsiveness to change measured by both questionnaires seem similar [19], all data were merged into 1 database.

We assessed QoL at baseline (up to 2 months before surgery) and 10–14 months after surgery. For inclusion, at least 50% of the questions of each domain had to be filled in when using the SF-36 and 100% when using the SF-12. For each patient we calculated an increase, decrease or no change in QoL at 1 year after surgery compared to baseline. The minimal clinically important difference (MCID) was set at 5 points: an increased QoL was defined by an increase in the component score >5 points, a decrease was defined by a decrease in score >5 points, and no change in QoL was defined by a < 5 point decrease or increase in score [20]. We defined as responders patients who completed both the preoperative and follow-up questionnaires. Non-responders were patients who completed only the preoperative questionnaire. We compared demographics, comorbidity, surgical data and preoperative QoL between the responders and non-responders to evaluate the generalizability.
Secondary outcomes were postoperative complications including surgical re-exploration [13], deep sternal wound infection [21], renal failure within 30 days after surgery [14] and stroke within 72 h after surgery [22]. Coronary reintervention and myocardial infarction were measured up to 1 year after surgery [13]. Definitions of complications are included in the Supplementary Material Section S1 checklist.

Analyses

Characteristics of patients are presented as proportions (with percentages) for dichotomous variables. Differences in dichotomous variables between the age groups were tested using the \( \chi^2 \) test or the Fisher’s exact test. The analysis of variance was used, with multiple comparison (Bonferroni correction) for analyses of age groups. Differences between summary scores at baseline and at 1-year follow-up were tested using a paired t-test. On the basis of a recent study concerning MCID in SF-36 scores, sensitivity analyses were conducted using an MCID of 4 points [23]. The linear regression analysis was used to evaluate the impact of age (independent variable) on the difference in QoL (dependent variable). Univariable analyses were used to identify possible deteriorating subgroups based on comorbidities at baseline; age was always included as the independent variable in the model, because this was our variable of interest. All variables with \( P < 0.1 \) in the univariable analyses were included in the multivariable model. All analyses were tested 2-sided, and variables with \( P \)-values of <0.05 were considered statistically significant. All data were analysed using SPSS version 23.0 (IBM Corp. Released 2015. IBM SPSS Statistics for Windows, Version 23.0. Armonk, NY).

RESULTS

A total of 8643 patients underwent an elective CABG procedure in the 3 participating centres. Of them, both the preoperative and the postoperative quality-of-life assessments were completed (responders) in 2606 patients (30%).

Characteristics of the patients

Table 1 presents all baseline, operative and postoperative characteristics of the study population. The proportion of women increases with age (\( P < 0.001 \)). A greater proportion of patients aged 65–79 years suffered from diabetes, pulmonary and/or arterial vascular disease. Patients aged \( \geq 80 \) years more frequently had reduced left ventricular function (\( P = 0.010 \)) and renal disease prior to surgery (\( P < 0.001 \)). During hospitalization, the incidence of stroke was higher in patients aged 65–79 years (\( P = 0.040 \)). We observed no significant differences between the 3 age groups concerning any of the other postoperative complications.

Quality of life

Mean MCS and PCS scores at baseline and at 1-year follow-up are presented in bar charts per age group (Fig. 1). All subscale scores are provided in the Supplementary Material, Section S3. Differences in QoL between baseline and 1 year after surgery are presented in Fig. 2A and B. We observed a decrease in physical health 1 year after CABG (>5 points) in 15% of patients younger than 65 years, in 15% of patients between 65 and 79 years and in 16% of patients \( \geq 80 \) years (\( P = 0.92 \); Fig. 2A). We registered a decrease in mental health 1 year after CABG (>5 points) in 20% of patients aged <65 years, in 20% of patients aged 65–79 years and in 29% of patients aged \( \geq 80 \) years (\( P = 0.039 \)) (Fig. 2B). Sensitivity analyses (using an MCID of 4 points) of differences in QoL revealed similar proportions of decreased physical and mental health components (Supplementary Material, Section S4A and B).
Association between age and quality of life

Table 2 shows the results of the regression analysis. Higher age was not significantly associated with a difference in QoL after 1-year follow-up (PCS $P = 0.054$ and MCS $P = 0.13$; respectively). Differences in QoL between men and women were also not significant. The multivariable regression analysis identified baseline PCS ($P < 0.001$), pulmonary disease ($P < 0.001$), a reduced left ventricular function ($P < 0.001$ for 30–50%) and renal disease ($P < 0.001$) as independent risk factors of a decreased physical QoL 1 year after surgery. The baseline MCS ($P < 0.001$) and a reduced left ventricular function ($P < 0.001$ for 30–50% ejection fraction) were identified as independent risk factors for decreased mental QoL 1 year after surgery. $R^2$ is 0.25 for the multivariable PCS model and 0.24 for the multivariable MCS model, meaning that ~25% variation in the dependent variable, i.e. change in QoL, can be explained by the independent variables included in the multivariable models.

Responders and non-responders

Non-responders ($n = 1644$) provided baseline data on QoL but no follow-up data. Baseline characteristics, operative characteristics and postoperative complications of responders and non-responders are listed in Table 3.

In the non-responder group, 37 patients (2.3%) died within <120 days, and a total of 75 patients (4.6%) died during the first year. Significant differences between the groups were BMI ($P = 0.042$), diabetes ($P < 0.001$), arterial vascular disease ($P = 0.003$) and renal disease ($P < 0.001$). Also, the incidence of
postoperative complications, such as stroke \( (P = 0.008) \) and renal failure \( (P = 0.006) \), was higher among the non-responders. Between both groups baseline PCS measurements were similar \( (P = 0.42) \), but we found statistically significant differences in baseline MCS \( (P = 0.001) \).

**DISCUSSION**

One year after CABG the quality of life of patients usually increases rather than decreases. The potential beneficial effects of CABG hold true especially for the physical component score of QoL. We observed less favourable effects of CABG on the mental component score. Age as a continuous variable was not significantly associated with a difference in QoL after 1 year of follow-up. Nevertheless, 1 out of 3 patients aged >80 years reported a decline in mental QoL. Several factors might explain why some patients report a decline in QoL. The results of this study show that baseline MCS and baseline PCS are both independent risk factors for a decreased QoL after CABG; in other words, patients with a higher QoL before surgery are more at risk of experiencing a decreased QoL after surgery. This finding, in statistics known as regression to the mean, is also observed in other studies \[7, 24, 25\], resulting in convincing evidence that a QoL assessment should be part of the preoperative examination, and expectations regarding QoL should also be discussed with the patient preoperatively. Another factor behind the decline in QoL in some patients could be side-effects of surgery, like a new comorbidity or reduced independence. Postoperative cognitive decline after CABG is reported with incidence rates varying between 30% and 60%, depending on cognitive tests, time of assessment and the patient population \[26, 27\]. Cognitive performance, QoL and the ability to perform daily activities reflect on patient-centred domains that are crucial to the patient’s retention of independence \[26\]. Furthermore, factors influencing QoL, like other health problems or loss of relatives, might have been experienced in these patients irrespective of cardiac surgery, and not at all been caused by the intervention.

In our study population, we found significant differences in baseline characteristics; more patients aged 65–79 years suffered from diabetes, pulmonary disease and/or arterial vascular disease. Also, the incidence of postoperative stroke was significantly higher in this age group. These findings however, do not account for the lower postoperative physical or mental QoL observed in our patients aged >80 years; this suggests that QoL relates to much more than just the presence of symptoms of disease, comorbidities and complications of surgery. The Constitution of the World Health Organization (WHO) defined QoL as ‘individuals’ perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns’ \[28\]; in other words, QoL is influenced by various physical, mental, social and environmental factors. This probably explains why independent ‘medical’ variables account for only 25% of the variance of QoL in both of our regression models. Future studies to compare the QoL of patients after surgery with patients after less invasive treatments (e.g. medication or percutaneous interventions) would provide valuable knowledge about the real harms and benefits of surgery on elderly patients and the impact on their QoL.

To assess the generalizability of our results we compared data from the responding and non-responding patients with CABG, as recommended by Noyez et al. \[10\]. We included information on demographics, comorbidity and the cardiac risk of all patients who could possibly have been included and on the patients actually included. Compared to the responding patients the non-responders had a higher prevalence of several comorbidity risk factors. A recent study suggested that the so-called non-responders in studies evaluating QoL after cardiac surgery may be older, be at higher operative risk and have a lower preoperative QoL; these factors may result in a positive overestimation of change in

Adjusted univariable and multivariable association between age and difference in the physical or the mental component score.

Beta: unstandardized regression coefficient; CABG: coronary artery bypass grafting; CI: confidence interval; LVEF: left ventricular ejection fraction; MCS: mental component summary; PCS: physical component summary.
QoL for the total population [29]. This also seems to apply to our study meaning that in the total population of patients with CABG, the number of patients with decreased mental well-being might be higher. However, compared to the QoL data from an age-matched control group of Dutch inhabitants, data from our patients resulted in remarkably high PCS and MCS scores (mean PCS 54.1 vs 50.4 and mean MCS 60.0 vs 52.5 for responders vs the general population) [30].

Our multicentre study also has important limitations. First, the number of patients with total available QoL data is low (30%), and reasons for the lack of pre- and/or postoperative data remain unclear. All data were collected by e-mail or a written survey, which might have led to reporting bias. A more personal approach (e.g. follow-up by telephone or at the outpatient clinic) might have led to higher response rates. For the non-responders, we chose to include only patients with complete preoperative QoL information, because these are the only patients from whom we could expect 1-year QoL data. Second, we lack information on preoperative mental health, discharge destination, participation in a rehabilitation programme and other events influencing QoL upon 1-year follow-up (e.g. other health problems, dependency or loss of relatives). Third, we lack information on survival and QoL from patients who were not accepted for surgery.

The outcomes of our study show that although most patients experience an improved physical and mental quality of life, a relevant proportion of patients deteriorate in mental health. Because in vulnerable elderly patients a small decline can have important consequences for their daily lives, such as loss of independence, it is imperative to discuss this issue during preoperative counselling.
