ABSTRACT

Background: Breath tests may diagnose tuberculosis (TB) through detecting specific volatile organic compounds produced by Mycobacterium tuberculosis or the infected host.

Methods: To estimate the diagnostic accuracy of breath test with electronic-nose and other devices against culture or other tests for TB, we screened multiple databases until January 6, 2019.

Findings: We included fourteen studies, with 1715 subjects in the analysis. The pooled sensitivity and specificity electronic-nose were 0.95 (95% CI 0.82–0.97) and 0.93 (95% CI 0.82–0.97), respectively, and no heterogeneity was found. The sensitivity and specificity of other breath test devices ranged from 0.62 to 1.00, and 0.11 to 0.84, respectively.

Interpretation: The low to moderate evidence of these studies shows that breath tests can diagnose TB accurately, however, to give a real-time test result, additional development is needed. Research should also focus on sputum smear negative TB, children, and the positioning of breath testing in the diagnostic work flow.

Funding: The authors received no specific funding for this work.

1. Introduction

Tuberculosis (TB) is the leading infectious cause of morbidity and mortality globally [1]. It spreads easily by air, with inhalation of infected droplets exhaled, coughed or sneezed by individuals affected with contagious forms of pulmonary TB. Approximately 23% of the world’s population is infected with TB bacteria, and 5–15% will suffer from TB at some point in time [1,2]. Diagnostic delay is a major concern in TB control: there is an average loss of one to three months delay between the first day that patients present to the health care system, and the moment of diagnosis [3,4]. In 2017, there was a gap of 3.6 million between notifications of new cases and the estimated number of incident cases [1], indicating a huge underreporting and under-diagnosis of TB cases. In response, the World Health Organization (WHO) launched an initiative to detect many more people with TB in the next few years [1].

The WHO criteria for pulmonary TB (PTB) diagnosis include clinical symptoms and isolation of M. tuberculosis from sputum by culture or by molecular assays as the line probe assays (LPAs), or detection of acid-fast bacilli by sputum smear microscopy (SSM) if culture or LPAs is unavailable, or – for smear-negative PTB patients - with chest radiography (CXR) showing abnormalities consistent with active PTB [5]. Meanwhile, for extra-pulmonary TB (EPTB), the diagnosis is based on at least one specimen with confirmed M. tuberculosis or histological, or clinical evidence consistent with active EPTB, followed by a clinician’s decision to treat with TB chemotherapy [5].

CXR implies radiation exposure and has low specificity [6], while SSM lacks sensitivity since the threshold of TB detection is high [7]. Furthermore, SSM can only detect TB in patients in advanced stage; it is less sensitive in Human Immunodeficiency Virus (HIV)-infected individuals, and does not differentiate between MTB and non-tuberculosis mycobacterial (NTM) infection [8,9]. Culture currently is the reference standard [5]. It needs only 10–100 MTB bacilli to establish a diagnosis, however, the laboratory turn-around time is long (two to eight weeks) [1].

Other sputum-dependent tests have been developed more recently, i.e. nucleic acid amplification techniques which allow for fast identification of MTB as well as rapid assessment of rifampicin susceptibility (such as GeneXpert® MTB/RIF (Cepheid, USA) and Truenat MTB assays® (Molbio Diagnostics, India)), LPAs (Hain Lifescience, Germany).
of breath [24]. GC/MS requires complex equipment, operation skills, and a well-conditioned environment, especially to record concentration differences of VOCs specific for TB [15–17,25,26], and different studies report different VOCs [17,25–27]. The electronic-nose has an array of sensors that identifies a pattern of VOCs without considering the specific composition of VOCs.

There has not been a systematic review regarding the accuracy of electronic-nose equipment in diagnosing TB from patients’ breath. We also explored other types or devices of breath tests, such as GC/MS, because there has been a rapid development in this field since the previous review [13].

To examine the accuracy of electronic-nose and other devices in diagnosing TB from patients’ breath, we reviewed the diagnostic test accuracy (DTA) studies that assessed the sensitivity and specificity of electronic-nose and other devices in diagnosing TB in patients with TB or suspected of having TB.

2. Methods

2.1. Protocol and registration

Methods of the analysis and inclusion criteria were documented in a protocol, and registered in PROSPERO (CRD42019132895).

2.2. Eligibility criteria

We included the DTA studies with participants of any age with TB or suspicion of TB. Diagnosis of TB was based on the WHO guideline [5]. The index test was a breath test, the comparator being sputum smear microscopy, chest radiography, culture, Gene Xpert, pleural biopsy, or a Composite Reference Standard (CRS).

2.3. Information sources

Studies were identified by searching electronic databases, i.e. Pubmed (1946–present), Embase (1946–present), Web of Science (1946–present), Medline (1946–present), clinicaltrials.gov, and WHO International Clinical Trials Registry Platform (ICTRP). Cochrane database was also reviewed. No limits were applied for language. The last search was run on 6 January 2019. A.M.S. and D.D.P. conducted the search. We also attempted to acquire any missing information on results from the investigator of articles included in this review, i.e. Marcel Bruins [22,23].

2.4. Search strategy and selection criteria

The PRISMA statement was followed for the systematic search [28]. The search strategies used terms such as “tuberculosis”, “diagnosis”, “breath test”, “electronic nose”, and “volatile organic compound”. Appendix 1 shows a detailed description of the search strategies. Studies were included if the subject was human, and were published from 1946 to present (6 January 2019). Abstracts of conferences were included. We excluded unpublished data, duplicate studies, reviews, and case reports. In addition, we hand-searched related articles from the reference lists, and trials registries, i.e. clinicaltrials.gov and WHO ICTRP.

2.5. Study selection

Eligibility assessment of titles and abstracts was performed independently by 2 investigators (A.M.S. and D.D.P.) based on the PICO5 criteria (Population = patients with TB or suspected with TB; Index test = breath test by electronic nose or other devices; Comparator = other tests for TB; Outcomes = sensitivity, specificity based on culture or WHO guidelines for TB diagnosis if culture result was not available; Study design: diagnostic test accuracy). Disagreements between investigators were resolved by consensus, or involving a third investigator (T.S.W.) when consensus was not reached. Full-text articles were then

and Nipro, Japan) to detect TB and resistance to first and second line anti-TB drugs, and TB LAMP (Eiken, Japan) for detection of TB [1]. However, LPAs and TB LAMP are not universally available or affordable, and even though Xpert MTB/RIF is provided at reduced price for low-middle income countries [1], it is not portable and needs stable electricity supply, limiting its use in highly burdened, remote settings in low- and middle income countries. One third of TB suspects have difficulty to collect an adequate quality sputum sample [10]. Therefore, a non-sputum based test would be a tremendous asset. Several non-sputum based tests are in development, such as urinary lipoarabinomannan for patients with TB-HIV coinfection, computer-aided detection systems [1], pediatric stool processing prior to Xpert [11], blood host marker, skin patches, and breath tests [12].

Breath tests have several advantages - non-invasive, potentially point-of-care, easy-to-perform, fast, and convenient [13]. Infections change the host metabolism producing distinct volatile organic compounds (VOCs) [14], and Mycobacterium tuberculosis (MTB) produces several VOCs [15–17], which can be detected from the breath. There are two approaches to analyze breath specimens - chemical and physical techniques. Examples of chemical techniques are gas chromatography combined with mass spectrometry (GC/MS), immunosensor and bio-optical technology, and electronic-nose with sensors that identify chemical interactions between VOCs and the sensor surfaces [18–23]. Physical techniques measure a physical property of the molecule, such as Field Asymmetric Ion Mobility Spectrometry (FAIMS) that measures movement of ionised molecules

Evidence before this study

The standard tests to diagnose tuberculosis (TB) such as culture and PCR, have high sensitivity, while sputum smear microscopy has only moderate sensitivity. These tests are not point-of-care, are sputum-dependent, and prone to laboratory fallacy, and need trained laboratory personnel. There is increasing evidence that analysis of exhaled breath could be used to diagnose TB. There are two approaches to analyze breath specimens - chemical and physical techniques. Examples of chemical techniques are gas chromatography combined with mass spectrometry (GC/MS), immunosensor and bio-optical technology, and electronic-nose with sensors that identify chemical interactions between VOCs and the sensor surfaces. The electronic nose has been used for diagnosis of various diseases, i.e. asthma, Chronic Obstructive Pulmonary Disease (COPD), urinary tract infection, lung cancer, and brain cancer. There has not been a systematic review regarding the accuracy of electronic-nose equipment in diagnosing TB from patients’ breath. We explored the whole array or devices of breath tests, including GC/MS, because there has been a rapid development in this field since the previous review.

Added value of this study

This study provides evidence on the sensitivity and specificity of breath test in diagnosing TB.

Implications of all the available evidence

These low to moderate strength of evidence studies show that an electronic nose had high sensitivity and specificity, while other devices had moderate to high sensitivity and low to moderate specificity. Further improvements are needed before breath test devices can be introduced into the routine TB diagnostic work flow.

Added value of this study

This study provides evidence on the sensitivity and specificity of breath test in diagnosing TB.

Implications of all the available evidence

These low to moderate strength of evidence studies show that an electronic nose had high sensitivity and specificity, while other devices had moderate to high sensitivity and low to moderate specificity. Further improvements are needed before breath test devices can be introduced into the routine TB diagnostic work flow.

Research in context

reviewed by A.M.S. and D.D.P. with a critical appraisal sheet taken from Joanna Briggs Institute Reviewers' Manual 2015 [29] which was developed based on the Quality Assessment of Diagnostic Accuracy Studies (QUADAS)-2 approach [30]. Resolving disagreements was conducted in the same manner. We then analysed the outcomes from the remaining relevant research articles.

2.6. Data collection process

A data extraction sheet was developed based on Joanna Briggs Institute Reviewers' Manual 2015 [29]. We pilot-tested it on ten randomly-selected included studies, and refined it accordingly. The two investigators (A.M.S. and D.D.P.) extracted the data from included studies. Disagreements were resolved by discussion between the two investigators; if no agreement was reached, a third investigator (T.S.W.) was involved.

2.7. Data items

Information was extracted from each included study on: (1) characteristics of study participants (demographic description, i.e. age, sex, inclusion and exclusion criteria; participant groups); (2) type of intervention (breath test with electronic nose or other devices versus other tests for TB); (3) type of outcome measures (sensitivity, specificity); (4) funding sources.

2.8. Risk of bias in individual studies

An assessment of risk of bias was conducted with the modified version of the QUADAS tool for Cochrane reviews [31] in a blind manner. Assessments were completed independently by two investigators (A.M.S. and D.D.P.), and disagreements were resolved by consensus, or involving a third investigator (T.S.W.) when consensus was not reached.

2.9. Summary measures and data analysis

The primary outcome measures were sensitivity and specificity of breath test to diagnose TB using culture, or the criteria mentioned in the WHO guideline for TB diagnosis if culture result was not available, as the reference [5]. The secondary outcome measures were Positive Likelihood Ratio (PLR), Negative Likelihood Ratio (NLR), and Diagnostic Odds Ratio (DOR). Sensitivity was defined as probability that a test result would be positive when the disease is present (true positive rate), specificity was the probability that a test result would be negative when the disease was absent (true negative rate). PLR described how many times positive index test results were more likely in the diseased group compared to control, NLR described how many times negative index test results were less likely in the diseased group compared to control, and DOR described how many times the odds were higher of obtaining a test positive result in a diseased compared to control [32]. We calculated pooled sensitivity, specificity, PLR, NLR, and DOR with 95% confidence intervals. We assessed heterogeneity and inconsistency for the pooled estimates by the Cochrane Q and I² statistic [33], and if there was heterogeneity, we conducted subgroup analysis to find the sources [32]. We used bivariate hierarchical random effects logistic regression models methods for meta-analysis of DTA to generate the Summary Receiver Operating Characteristics (SROC) curve with point estimates and their 95% confidence region from all study sources. All analyses were performed with STATA (version 15 SE; Stata Corporation, College Station, TX, USA). Stata commands of “metandi” and “metandiplot” are used to facilitate calculating the summary of the fitted point and the curve with 95% prediction region [34].

2.10. Risk of bias across studies

Risk of bias was assessed according to QUADAS items [35]. We had earlier planned to make a funnel plot to assess the publication bias within studies, but we decided not to, as it was not recommended by the Cochrane Handbook considering that it might mislead the interpretation of the publication bias assessment [32]. We also looked for missing data from the included studies that could produce selective reporting bias.

3. Results

3.1. Study selection

A total of 14 studies were identified for inclusion in the review. The search of Pubmed, Embase, Web of Science, Medline, clinicaltrials.gov, ICTR, and Cochrane databases provided a total of 391 studies. After adjusting for duplicates, 239 remained. Of these, 225 studies were discarded because these papers did not meet the criteria. The full text of the remaining 20 studies was examined in more detail. Fourteen studies met the inclusion criteria and were included in the systematic review. By checking the references, relevant papers and searching for studies that have cited these papers, no additional studies that met the criteria for inclusion were identified.

3.2. Study characteristics

All fourteen studies finally selected for the review were published in English. Table 1 shows characteristics of the studies. Number of subjects analysed ranged from 40 to 251 subjects per study. Only three studies included children (aged ≥13 years); the others included only adults. All studies were carried out prospectively. 9 out of 14 studies (64·3%) employed a case-control study design (for studies that consisted of training and validation phases, we only assessed the study design in the validation phase as it reflected the performance of the device). Most of them were conducted in hospitals and lung clinics; six studies were conducted in Africa, two in Asia, two in South America, one in Europe, two in transcontinental countries (Egypt and Russia), and one in both Asia and Europe. (See Fig. 1.)

3.3. Risk of bias

Fig. 2 summarizes the risks of bias and applicability concerns of studies. Only five studies specified that they involved consecutive series of patients; the other studies did not describe the process of sampling and used case-control study design. However, due to the nature of these pilot studies, case-control is commonly used, thus we assessed the risk of bias in terms of ‘patient selection’ as medium. All studies reported a clear definition of a positive test using a reference diagnostic test, but only six ensured adequate blinding, six did not mention concealment, and the subjects in the validation group in two studies overlapped with the training group (medium to high risk of bias concerning ‘index test’). In terms of ‘flow and timing’, only six out of 14 studies mentioned the exact time interval between the index test and reference test, but the sputum sample could be collected anytime even on the same day of the assessment using the index test (low risk of bias). All of included studies had complete verification for positive reference test, however not all subjects in one study used the same reference test. Eight studies used the gold standard, which is culture, while other 6 studies also used other examinations beside culture (low to medium risk of bias for reference standard). In summary, 12 studies were considered having a medium risk of bias or raised applicability concerns for at least one item of the QUADAS-2 tool.

3.4. Test accuracy

The total number of subjects included in the analysis of sensitivity and specificity of breath tests (validation phase) amounted to...

1715 subjects (Table 1). The sensitivity and specificity of each test is shown in Table 1. As the number of breath test devices other than electronic-nose was insufficient for grouping, the statistical analysis was only calculated for the electronic-nose. The Q and I² of electronic-nose in diagnosing TB were p = 0.23 and 0 (95% uncertainty intervals: 0–100), respectively. The pooled sensitivity and specificity of electronic-nose in diagnosing TB were 0.92 (95% CI: 0.82–0.97) and 0.93 (95% CI: 0.88–0.96), respectively (Fig. 3). The PLR, NLR, and DOR were 13.4 (95% CI: 7.2–24.9), 0.08 (95% CI: 0.03–0.20), and 162 (95% CI: 41–634), respectively. Fig. 4 shows the summary receiving operating characteristics for these studies. The area under the curve (AUC) of electronic-nose was 0.97 (95% CI: 0.93–1.00). Meanwhile, the sensitivity and specificity of breath test devices other than electronic nose ranged from 0.62 to 1.00, and 0.11 to 0.84, respectively.

4. Discussion

The pooled sensitivity and specificity of electronic-nose in diagnosing TB, either pulmonary or extrapulmonary, were high. There is no
Fig. 2. Summary of QUADAS-2 assessments of included studies. Patient selection: describes methods of patient selection; index test: describes the index test and how it was conducted and interpreted; reference standard: describes the reference standard (gold standard test) and how it was conducted and interpreted; flow and timing: describes any patients who did not receive the index tests or reference standard or who were excluded from the 2 × 2 table, and describes the interval and any interventions between index tests and the reference standard [30].
heterogeneity, indicating that the variability among studies that diagnose TB with electronic-nose was due to chance. Other devices had moderate to high sensitivity and low to moderate specificity. The strength of evidence within all 14 studies was low to moderate. Five studies only included subjects representing two extreme sides of the clinical spectrum of TB disease (healthy controls without any TB symptoms, and symptomatic, treatment-naïve, smear positive pulmonary TB cases) [18,21,36–38]. Meanwhile, different stages of TB disease are characterized by dynamic metabolic changes within pathogen and host and their interactions, thus different stages of TB disease may generate different breath test results [21]. In addition, around 20–25% of the world population have latent TB [39], and the event of relapsed TB in the high-TB burden countries is not uncommon. Therefore, these studies had limited generalisability and clinical applicability, and might also produce bias as the results might be over-estimated, thus these assumptions might be not valid for our review. Ideally, besides being able to identify the VOCs produced by either the host or the bacteria, the breath test’s sensors should ideally be able to identify different signals in different stages of TB disease. Only seven studies included other pulmonary infections as controls [19,20,22,24–42], while a diagnostic test is typically needed in this population, to identify the TB afflicted among the suspects.

Breath prints are influenced by various factors, which are divided into physiological factors (age, sex, food, beverages), pathological and disease-related conditions (smoking, comorbidities, medication), and sampling-related issues (bias with VOCs in the environment) [43]. Older age changed breath prints in patients with lung cancer [44], males had higher level of isoprene than females [45], several beverages and poultry meat could be...
identified with an electronic-nose [46–50], and patients with high body mass index (BMI) had more false-positive test results than patients with normal or low BMI [23]. Smoking increased the levels of several VOCs, i.e. benzene and pentane [51], while these two VOC markers were observed in the culture and breath of TB patients [17]. Apart from those mentioned factors, VOCs might be also influenced by genetic profiles [23]. Thus, in the analysis of the breath test, confounding or modifying effects from these factors should always be considered. In only four of the reviewed studies, at least one of these factors were taken into account [18,21,23,37]. Furthermore, there were only three studies including children in their study population, and children were also not exclusively enrolled [18,22,40], while age may influence the breath test result [44].

In several electronic-nose studies, the exhaled breath was collected into a bag/tube with the specimen investigated later [19,21,22,36]. Using bags for collection may be more useful in the flow of healthcare in a clinic, however, it might change the composition of the sample because the VOCs bind with the sample-bag material, and the bag material releases background emission of several pollutants [52]. Samples should be also examined in six hours from the collection time [52], thus it adds a burden and complicates the diagnostic process. As far as the portable sensing technology is not yet specific enough for VOCs associated with TB, we recommend to avoid using bags for sample collection. In addition, although the sensors in an electronic-nose can capture abundant amounts of information, most of them do not have sensitivity as high as other techniques [53], thus to improve the sensitivity, pre-concentration techniques, such as absorption of breath samples onto a solid phase, needs to be performed. Several studies in this review used micro-extraction (SPME) or Tenax as the pre-concentration technique [19,23,40], while other studies did not mention it in their Methods section.

To develop a robust algorithm to enable real-time measurements, an electronic-nose needs a prior knowledge of the data (training phase). Ideally, to avoid a fallacy in breath test analysis due to confounding variables, artefacts, and statistical errors, a training phase should include a large number of study subjects, so that the number of subjects will be bigger than the number of breath test variables/features, and the data can be divided into a training and validation set [54]. However, if the population is small, a leave-one-out cross validation is usually used in the training phase, i.e. only one subject is used for validation purposes, while the others are used for training [54]. The device performance can be assessed more objectively if the next stage (validation phase) is carried out in subjects who are not involved in the training phase. In only three out of six studies with electronic-nose, the validation phase used independent subjects from the training phase [19,21,36]. In addition, a large number of subjects in the training phase is of great importance to expose the device with large diversity in breath patterns from true-positive study subjects. Only then, the device can recognize breath samples in the validation phase with high accuracy. For an electronic-nose device, to match a pattern correctly, the pattern must be known before.

The diagnostic accuracy of an electronic-nose can only be determined reliably if the TB status can be classified with high certainty since the analysis of breath test completely depends on the correct classification of the study samples in the training phase. Therefore, a reference test should be as ‘gold’ as possible, approaching the highest sensitivity and specificity. When the gold standard is imperfect, the positive test results from an investigated diagnostic tool may be considered as false-positives, thus the accuracy of this diagnostic tool will be underestimated. In this review, eight studies used only culture as the reference test for diagnosing pulmonary TB, while the other six studies used culture or other supporting data when the culture result was negative. In our opinion, the use of other supporting data to improve the accuracy of culture is justifiable because culture is also prone to laboratory error. In addition, follow-up should be employed to ensure that the diagnosis made was correct. A previous study has shown that follow-up could help to cover the weakness of culture and improve its accuracy [55].

For other breath test devices, the selected ion flow tube-mass spectrometry (SIFT-MS) becomes the preferable option as it is faster and has higher sensitivity than GC–MS. [56] Ideally, the chemical platform for chemical breath analysis would have online identification of specific analytes without the need for pre-concentration and should be able to analyze small volatiles (in the ppt–ppq range) [53]. Currently with GC–MS, samples still need to be pre-processed before testing. To validate the biomarkers that were found through GC–MS or other spectrometries, a large cohort study is needed. The use of oral urea administration in diagnosing TB may not be ideal because of low lung concentration, and is confounded by the presence of H. pylori in the gut [38]. However, the administration of urea by inhalation for diagnosing TB warrants investigation. Detection of antigen in cough was shown to have moderate sensitivity and specificity that was suspected as a result from the variation of antigen level in cough during the day, thus it was suggested to conduct the breathalyzer test several times in a day [20]. However, repeating a test several times in one day takes time and is therefore impractical. Furthermore, prior to sputum collection, patients needed to have nebulized therapy, thus limiting its use for a point-of-care device in remote areas. This device might also be projected as an add-on test for sputum smear microscopy, which would not provide an advantage over sputum-dependent sputum smear microscopy and culture.

The existing tests have high sensitivity, such as culture and PCR [1], or very high specificity, such as Gene Xpert [57], or moderate sensitivity, such as sputum smear microscopy [1,35]. However, these highly sensitive tests are not point-of-care, are sputum-dependent, prone to laboratory fallacy, and need trained laboratory personnel. With the high sensitivity, easy operation, point-of-care, and hand-held form, the breath test might be potentially used as a screening method rather than a diagnostic tool. Cases that are positive by breath test, could be referred for the tests which are more specific, probably more expensive, and laboratory-based, such as Gene Xpert. To date, there have been no studies that investigate the breath test as a screening tool.

A challenge for the breath test development in the future is to detect TB cases with negative sputum smear. Negative sputum smear was shown to have correlation with a misdiagnosis of TB [55]. Another challenge is to investigate whether the breath test can accelerate the diagnostic process and lower its cost. A point-of-care automated thermal desorption, gas chromatography and mass spectrometry (ATD-GC-SAW) costs $20,000 [18], while an electronic-nose based on metal-oxide sensors has an advantage of mass production at low cost. Analysis of a breath VOC sample with a point-of-care ATD-GC-SAW takes six minutes [18], whilst currently the analysis time with electronic-nose still takes several days or weeks as the data needs to be sent to the device producer before obtaining the diagnosis. Once the pattern recognition technique algorithm is fully trained, the results should be generated automatically in seconds. For further optimization of the sensors, specific VOCs in different stages of the disease need to be determined. The use of highly selective sensors that target these VOCs may increase the sensitivity and specificity. Finally, as the group of patients that need non-sputum-based tests most are children, the sensitivity and specificity of breath test exclusively in children needs to be extensively investigated.

Our review has some limitations. Only a limited number of studies concerning breath test using electronic-nose for diagnosing TB were available. Within the identified studies with breath test devices other than electronic-nose, we were not able to conduct meta-analysis by the type of devices because studies were few. Several studies only included treatment-naïve, smear positive pulmonary TB cases, thus hindering conclusions on the sensitivity and specificity of breath test for all stages of TB, and this may introduce overestimation of sensitivity and specificity. Nine out of 14 studies had an unclear risk of bias concerning patient selection, and five had an applicability concern on one or two domains.

5. Conclusions

These low to moderate strength of evidence studies show that breath tests have potential to screen for TB. However, it still needs
further improvement, with a more robust trained pattern recognition technique to give real-time measurements. An ideal breath test should be accurate, fast, easy-to-use, point-of-care, and distributed with low price, so that it can be used not only in clinics, but also for door-to-door screening in remote areas, where TB diagnosis still faces great challenges.
