ABSTRACT: Genetically determined myoclonus disorders are a result of a large number of genes. They have wide clinical variation and no systematic nomenclature. With next-generation sequencing, genetic diagnostics require stringent criteria to associate genes and phenotype. To improve (future) classification and recognition of genetically determined movement disorders, the Movement Disorder Society Task Force for Nomenclature of Genetic Movement Disorders (2012) advocates and renews the naming system of locus symbols. Here, we propose a nomenclature for myoclonus syndromes and related disorders with myoclonic jerks (hyperekplexia and myoclonic epileptic encephalopathies) to guide clinicians in their diagnostic approach to patients with these disorders. Sixty-seven genes were included in the nomenclature. They were divided into 3 subgroups: prominent myoclonus syndromes, 35 genes; prominent myoclonus syndromes combined with another prominent movement disorder, 9 genes; disorders that present usually with other phenotypes but can manifest as a prominent myoclonus syndrome, 23 genes. An additional movement disorder is seen in nearly all myoclonus syndromes: ataxia (n = 41), ataxia and dystonia (n = 6), and dystonia (n = 5). However, no additional movement disorders were seen in related disorders. Cognitive decline and epilepsy are present in the vast majority. The anatomical origin of myoclonus is known in 64% of genetic disorders: cortical (n = 34), noncortical areas (n = 8), and both (n = 1). Cortical myoclonus is commonly seen in association with ataxia, and noncortical myoclonus is often seen with myoclonus-dystonia. This new nomenclature of myoclonus will guide diagnostic testing and phenotype classification. © 2019 The Authors.

Key Words: genetics; hyperekplexia; myoclonic epilepsy; myoclonus; nomenclature

Myoclonus is a hyperkinetic movement disorder characterized by sudden, brief, involuntary jerks of a single or multiple muscles.1-3 It can be caused by muscle contraction (positive myoclonus) or sudden interruption of muscle activity during intended isometric contraction (negative myoclonus).4 The myoclonic jerks can be difficult to observe, and they can be present in various neuromuscular disorders, including myopathies, neurogenic disorders, and metabolic disorders. Myoclonus can also be a result of genetic factors, and it can be associated with a wide range of clinical presentations, including ataxia, dystonia, and cognitive decline. The new nomenclature proposed in this article will help guide clinicians in diagnosing and classifying myoclonus syndromes and related disorders.

to distinguish from other hyperkinetic movement disor-
ders.\(^5\) Electrophysiological testing has proven helpful for
discriminating myoclonus from other hyperkinetic move-
ment disorders and for classifying the myoclonus subtype.\(^6\)
Myoclonus can be classified based on anatomical origin: corti-
cal, subcortical (or noncortical\(^7\)), spinal, and periphe-
ral myoclonus.\(^8\) So far, in genetic myoclonus syndromes
only cortical (CM) and subcortical subtypes have been
described.\(^8\)

Determination of the etiology of myoclonus is challeng-
ing, and recently, a novel diagnostic 8-step algorithm was
proposed to help clinicians accurately, efficiently, and
cost-effectively diagnose myoclonus.\(^9\) Once the acquired
forms and late-onset neurodegenerative disorders (such as
Alzheimer’s disease and parkinsonism disorders) of myo-
clonus are excluded in this diagnostic workup, a large
number of genetically determined disorders with wide
clinical variation remain. In almost all genetic syndromes,
myoclonus is not the sole feature, but it is accompanied
or even overshadowed by another movement disorder.\(^5\)
This is likely the reason systematic nomenclature similar
to PARK (for parkinsonism) or DYT (for dystonia) has
not been established for myoclonus. In many of the
suspected genetic myoclonus syndromes, the genetic cause
is (still) unknown, but next-generation sequencing (NGS)
has revolutionized molecular genetic diagnosis and has
produced an exponential increase in known genetic
causes and expansion of movement disorder phenotypes, includ-
ing myoclonus. However, NGS frequently produces
genetic variants for which pathogenicity is unclear. This
emphasizes the importance of good clinical phenotyping
and weighting of NGS results in the context of the pre-
senting clinical syndrome.

In 2012, the International Parkinson and Movement
Disorder Society Task Force for Nomenclature of Genetic
Movement Disorders was established to revise the system
of locus symbols, as the current movement disorders sys-
tem had become outdated with the advances in NGS, the
lack of established criteria for conferring locus symbols,
or ongoing revision of the list.\(^9\)

Here we present a new myoclonus nomenclature. We
also include groups of related disorders that can present in
the outpatient clinic of a movement disorder special-
ist with jerks as a prominent symptom. First, there are
the hyperekplexias, as the excessive startle reflex closely
resembles reticul relex myoclonus, both clinically
and neurophysiologically.\(^10\) Second are the genetic epilepsy
syndromes with myoclonic jerks, specifically the epileptic
encephalopathies. Patients with myoclonic epilepsy enceph-
aloopathies exhibit, next to their clear epileptic attacks, often
spontaneous, reflex or action myoclonus, with evidence of a
cortical origin. These cortically driven epileptic jerks resemble
isolated cortical myoclonus, as both are characterized by
short-lasting (<100-millisecond) jerks with a cortical dis-
charge on the electroencephalogram (EEG). Historically, it
is not clear if there is a neurobiological distinction between
the 2 phenomena, and therefore we decided to include them
both in the current myoclonus nomenclature.

The first 2 papers of the task force included the pro-
posed nomenclature for genetic parkinsonism, dysto-
ния, autosomal-dominant and -recessive cerebellar
ataxia, hereditary spastic paraplegia, paroxysmal move-
dment disorders, neurodegeneration with brain iron
accumulation, and primary familial brain calcification.\(^1,2\) Here, we present the genetically determined
myoclonus syndromes nomenclature based on the same
principles, criteria, and recommendations.

**Methods**

**Inclusion**

Our recommendations are based on a systematic liter-
ature search. All articles regarding genetic causes of
myoclonus syndromes were identified by a PubMed,
Online Mendelian Inheritance in Man, and Textbook
search, including all the additional relevant references cited
in the articles found. The key search terms “myoclonus,”
“myoclonic epilepsy,” and “startle” were used in combi-
nation with the term “genetic causes.” For the period to
June 2015, we used our previously published systematic
review with the same search terms.\(^4\) In addition, an identi-
cal search was performed for the period between June
2015 and October 2018 to identify newly discovered
genes. All reviewed articles and abstracts were restricted to
those published in English.

Following the recommendations of the task force, the
criteria for gene inclusion are that mutations in the gene
must be causative (ie, risk factor genes were excluded),
and myoclonus must be a prominent feature. In deter-
mining the pathogenicity, no specific threshold for the
level of penetrance of a mutation was designated by the
Movement Disorder Society (MDS) Task Force and
was determined for each gene based on standards prev-
ailing in the field. In the field of myoclonus, we decided
that genes related to myoclonus or myoclonic epilepsy
with medium or low penetrance were excluded. In
Table 1 we included genetic disorders DYT-ANO3 and
CHOR-NKX2-1, although the penetrance of these
genes is reduced. The reason to include them is that the
previous nomenclature of the MDS Task Force decided
to include lower penetrance, as it is more common in
dystonic syndromes and these 2 genes present with the
clinical syndrome of myoclonus-dystonia.

Prominent myoclonus was present if either (1) the lit-
erature stated that myoclonic jerks were a prominent
feature of the phenotype, (2) the myoclonic jerks were
the main reason for disability, and/or (3) the myoclonic
jerks were the main focus of treatment. In addition to
this, the predominance of myoclonus in the disorder
had to be confirmed in the literature by a second inde-
pendent group of researchers.\(^1\)

+++ Severe/progressive presentation of symptom; +, mild presentation of symptom; −/+, symptom can be present or absent; − symptom is absent.

AMRF, action myoclonus renal failure; ARSACS, autosomal-recessive spastic ataxia of Charlevoix-Saguenay; BSM, brain stem myoclonus; CM, cortical origin of myoclonus; DEE, developmental and epileptic encephalopathy; DRPLA, dentate-rubro-pallido-luysianatrophy; EPM, progressive myoclonus epilepsy; FCMTE, familial cortical myoclonic tremor with epilepsy; FDFM, familial dyskinesia with facial myokymia; FENIB, familial encephalopathy with neuroserpin inclusion bodies; ICs, isolated cases; MCAHS2, multiple congenital anomalies-hypotonia-seizures syndrome-2; M-D, myoclonus-dystonia; MEAK, myoclonus epilepsy and ataxia from potassium (K+) channel mutation; MERRF, myoclonic epilepsy with ragged red fibers; SCM, subcortical origin of myoclonus; UN, myoclonic subtype is unknown; XLD, X-linked dominant; XLR, X-linked recessive.

<sup>a</sup>Myoclonic subtype could not be assigned according to the official criteria stated by Zutt et al (2018)<sup>83</sup>; therefore, the subtype stated in the literature was adopted but accentuated as presumed using an asterisk.

<sup>b</sup>Loss of the maternally inherited UBE3A gene.

<sup>c</sup>Recently, authors have proven the pentanucleotide repeat TTTCA (and TTTTA) to be causative of FCMTE in the intron of MYC-SAMD12 and MYC-RAPGEF2.<sup>12</sup> Although the authors believe the intronic pentanucleotide repeat to be pathogenic irrespective of the gene, we have stated the 2 genes that have been confirmed in the literature.

<sup>d</sup>The following additional genetic mutations are able to cause MERRF: mt-MTTL11 (OMIM 590090), mt-MTTH1 (OMIM 590040), mt-MTTS11 (OMIM 590080), mt-MTTS21 (OMIM 590085), mt-MTTF1 (OMIM 590070), mt-MTTW (OMIM 590095).1

<sup>e</sup>The following genes have been reported to cause a DS-like phenotype by 2 independent research groups: SCN1B (OMIM 600235), PCDH19 (OMIM 300460), GABRA1 (OMIM 615744).

<sup>f</sup>The phenotype of a combined myoclonus syndrome is characterized by multiple predominant movement disorders including myoclonus.

<sup>g</sup>Because of recent suggestions of the Task Force Nomenclature, the previously proposed prefix SCA for autosomal-dominant dystaxias was replaced by ATX, resulting in the replacement of prefixes of 2 genes, ATN1 and PRKCG. SCA-ATN1 has been changed to ATX-ATN1 and SCA-PRKCG to ATX-PRKCG.

<sup>h</sup>Patients diagnosed with a genetic defect of ASAH1 were described by Topaloglu et al (2016) as having subcortical myoclonic epileptiform abnormalities. However, based on the clinical characteristics we suspect a cortical origin of the myoclonic jerks and have classified this gene accordingly.

<sup>i</sup>Opposed to the previously assigned prefix CHOR in CHOR-PRNP, the prefix CHOR was removed, and the name was altered to PRNP, as this gene causes multiple phenotypes including myoclonus and in which chorea only dominates in a minority of cases.

Cognitive problems include both cognitive decline and psychomotor retardation. The myoclonic subtype was determined unknown if neither an official myoclonic subtype could be assigned or a myoclonic subtype was stated in the literature.
This adjudication process included 2 persons (S.V. and R.Z.). All genes included in the new nomenclature were reviewed by 6 experts within the field of myoclonus to reach a broadly supported consensus (H.S., J.C., S.B., P.T., T.K., M.T.).

**Classification**

Following the recommendation of the task force and to guide clinicians in daily practice, the genetic disorders were allocated based on clinical presentation into 1 of the following 3 groups: (1) *prominent myoclonus syndromes*, genetic disorders that present with prominent myoclonus in the majority of cases; (2) *combined myoclonus syndromes*, genetic disorders that present with prominent myoclonus and another prominent movement disorder (eg, dystonia/ataxia) in the majority of cases; and (3) *disorders that usually present with other phenotypes but can manifest as a prominent myoclonus syndrome*, genetic disorders that present with prominent myoclonus only in a minority of cases as part of the phenotypic spectrum of this disorder.

**Prefixes**

In accordance with the recommendations of the task force, the prefix MYC was given to genes in which myoclonus is a prominent feature in the majority of the patients. In addition, we added a second prefix to genes and consequently allocated it to the subgroup *combined myoclonus syndromes*, in which another movement disorder is an additional prominent feature, resulting in a double prefix if both movement disorders are prominent (eg, MYC/ATX-GOSR2). Overlapping genes with double prefixes were discussed among the appropriate experts from the MDS Task Force to reach consensus. The symbol prefix is followed by the gene name. For clarity and to allow comparison with former classifications, we provided the old locus symbol (eg, DYT11) in the last column of Table 1, when appropriate. Genes that present with myoclonic epilepsy were not given any prefix, because the dominant feature of the phenotype is epilepsy rather than a movement disorder.

**Additional Clinical and Electrophysiological Items**

A brief description of the clinical presentation of disorders linked to each gene is listed in Table 1 with special emphasis on the most common accompanying signs and symptoms including ataxia, dystonia, cognitive problems, or epilepsy. Furthermore, we added the myoclonic anatomical subtype, cortical or subcortical (ie, non-cortical), if known, for each genetic disorder based on reported clinical and electrophysiological features to further improve the classification of myoclonus. Experts have argued against the term “subcortical” myoclonus, as its anatomical origin is still undetermined; however, the term “subcortical” myoclonus will still be used in the new nomenclature because of the absence of a widely supported alternative. See Supplementary Table 1 for the anatomical classification criteria for myoclonus.

**Results**

**Gene Selection**

One hundred sixty-six genes linked to a myoclonus syndrome were found in the systematic literature review. An extensive overview of all genes associated with myoclonus with reason for inclusion or exclusion can be found in Supplementary Table 3, and see Figure 1 for an overview. Ninety-nine genes were excluded because of the absence of prominent myoclonus (n = 45), lack of confirmation of the phenotype with prominent myoclonus by a second independent research group (n = 31), and questionable pathogenicity (n = 23).

Sixty-seven genes were included in the new nomenclature for myoclonus syndromes (see Table 1). (1) In the subgroup *prominent myoclonus syndromes*, 3 genes were included; (2) in the subgroup *combined myoclonus syndromes*, 9 genes were included; and (3) in the subgroup *disorders that usually present with other phenotypes but can manifest as a prominent myoclonus syndrome*, 23 genes were included.

**Prefix Allocation**

The locus symbol prefix MYC was assigned to 22 genes. Genes in which the predominant phenotype showed wide heterogeneity or was dominated by epileptic or nonmotor symptoms were not assigned any prefix. For myoclonus epilepsy with ragged red fibers syndrome, only the most frequent causative gene (mt-MTTR) is listed. The remaining causative genes are stated in the caption of Table 1, as they are associated with a similar phenotype as mt-MTTR.
Additional Clinical and Electrophysiological Clues

The following most common accompanying signs and symptoms observed overall were cognitive decline in 90% (n = 60), epilepsy in 82% (n = 55), ataxia in 61% (n = 41), ataxia and dystonia in 9% (n = 6), and dystonia in 7% (n = 5). The anatomical location of myoclonic origin could be allocated in 64% of genes (n = 43) because of support from strong electrophysiological data, and in the cortex in 51% (n = 34), noncortical areas in 12% (n = 8), and both cortical and noncortical areas in 1% (n = 1) of all genes. Three of the 8 genes with jerks originating from non-cortical areas were classified as originating from the brain stem (hyperekplexia).

Discussion

In this article we propose a nomenclature of genetically determined myoclonus according to the new naming system presented by the MDS Task Force.1 This myoclonus list currently includes 67 genes. Thirty-five genes presented with prominent myoclonus syndromes, 9 with combined myoclonus syndromes, and 23 with disorders that usually present with other phenotypes but can manifest as a prominent myoclonus syndrome. Co-occurrence of movement disorders, especially ataxia and dystonia, was seen in almost all except for familial cortical myoclonus tremor with epilepsy (FCMTE, or BAFME, benign adult familial myoclonus epilepsy), hyperekplexia, and (myoclonic) epileptic encephalopathies. Epilepsy and cognitive decline were the most frequently observed accompanying clinical features for the disorders listed in this new nomenclature.

The literature search detected 166 genes linked to a myoclonus syndrome, but only 67 were used for the nomenclature list. Filtering using strict criteria (independent confirmation and predominant myoclonus) to arrive at a list of confirmed entities that can present with predominant myoclonus is meant to help the clinician with the selection of test procedures and assist in the interpretation of results of genetic testing.2 In our opinion, the requirement for independent confirmation by a second research group is an important criterion, as it diminishes erroneous genotype-phenotype linkages. At present, with the widespread use of NGS in research and clinical diagnostics, many potentially new myoclonus genes are reported. Still, we had to exclude 31 genes (19%) that require validation. A significant proportion of patients with myoclonus syndromes still remain unsolved (progressive myoclonus ataxias in 36%94 and progressive myoclonus epilepsies in 28%95), in which excluded genes could be considered.

A new clinical diagnostic approach in patients with myoclonus has recently been described.8 After establishing that the myoclonus in a patient has a genetic cause, Table 1 can be used as a diagnostic framework for physicians in clinical practice to select candidate genes for individual patients based on the absence or presence of accompanying signs and symptoms.

FCMTE/BAFME is the only genetically determined myoclonus syndrome with relatively pure myoclonus, although it is accompanied by infrequent epilepsy in a majority of but not all patients. This genetic disorder is caused by 2 recently confirmed genes (MYC-SAMD12 and MYC-RAPGEP2) with intronic expansions of non-coding TTTCA and TTTTA pentanucleotide repeats. It presents with a phenotype of benign CM with infrequent tonic-clonic and sometimes focal seizures. RNA-mediated toxicity resulting in diffuse loss of Purkinje cells in the cerebellum is suggested to be the underlying pathogenesis of this disorder.96,97 The potential role of the cerebellum in CM has been pointed out multiple times in the literature, supported by the frequent phenotypical co-occurrence of CM and cerebellar ataxia.98

Ataxia is the most common accompanying movement disorder in myoclonus syndromes (24 genes). Almost all patients in whom the genetic disorder consists of a combination of ataxia and myoclonus present with the clinical syndrome of progressive myoclonus ataxia (PMA) or progressive myoclonus epilepsy (PME). The most common and best characterized are Unverricht-Lundborg disease (MYC/ATX-CSTB), Lafora disease (MYC/ATX-EMP2A), neuronal ceroid lipofuscinosis (multiple genes), sialidosis (MYC/ATX-NEU1), and dentatorubral pallidoluysian atrophy (ATX-ATN1).99

The anatomical origin of myoclonus in most patients with ataxia is thought to be cortical. Clinically, cortical myoclonic jerks present typically in the distal limbs and face, jerks are provoked by action and are stimulus sensitive.93 Of the genetic disorders in which ataxia and myoclonus co-occur, we found that cortical origin was supported by strong electrophysiological evidence in 54% (n = 14), and it was suspected in 33% (n = 8). Mechanistic hypotheses for cortical myoclonus include: (1) loss of Purkinje cells with astrocytosis, resulting in disinhibition via the cerebellathalamico-cortical pathway, (2) neuronal cell loss in the dentate nuclei leading to impaired cerebellar projections to the cortex, or (3) a reduction in the concentration of γ-aminobutyric acid (GABA)-ergic synapses in the sensory-motor cortex.100 On a molecular level, most genetic disorders presenting with both ataxia and myoclonus have impaired posttranslational modification of proteins to which certain neuronal groups might be particularly vulnerable compared with others.100 This could play a role in the characteristic phenotype of PMA, including a fixed order of signs, starting with ataxia, subsequently CM, and eventually by infrequent epilepsy.94

Dystonia is the second type of prominent movement disorder accompanying myoclonus. The combination of myoclonus and dystonia is known as myoclonus-dystonia syndrome (M-D). The classical myoclonus-dystonia phenotype is based on genetic defects in the MYC/DYT-
SGCE gene in about 50% of cases. Other disorders that can give rise to a myoclonus-dystonia phenotype include MYC/DYT-KCTD17, DYT-ANO3, ATX-PRKCG, ATX-ATM, CHOR/DYT-ADCY5, CHOR-NKKX2-1, and maternal uniparental disomy with regions of heterodisomy and isodisomy on chromosome 7 (mUPD7), which is based on the loss of function of the SGCE gene.

The anatomical locus of myoclonus in M-D is subcortical. Clinically, the myoclonus and dystonia in M-D are located mainly in the trunk and proximal upper limbs, and the myoclonus is not stimulus sensitive. The noncortical origin of the myoclonus is supported electrophysiologically in 5 genetic disorders presenting with M-D (MYC/DYT-SGCE, MYC/DYT-KCTD17, DYT-ANO3, ATX-ATM, ATX-PRKCG) and unknown in 2 others (CHOR/DYT-ADCY5 and CHOR-NKKX2-1). The pathophysiology of subcortical myoclonus includes circuit abnormalities in the basal ganglia and involvement of the cerebellum. Disruptions in neurotransmission pathways have been hypothesized to play a role, particularly the unbalanced homeostasis of GABA, seratonin, and dopamine-related pathways. In contrast to myoclonus of cortical origin, cortical excitability and intracortical inhibition were found to be normal or less profoundly disturbed.

The overlap between types of accompanying movement disorders and the anatomical origins of the myoclonic jerks is remarkable. Currently, the anatomical origin can be assigned in only 64% of genetic disorders. We encourage movement disorder specialists to classify the subtype of myoclonus by a thorough clinical description (eg, distribution, stimulus sensitivity) of the myoclonic jerks and if possible electrophysiological testing (eg, corticomuscular coherence or jerk-locked back-averaging). We realize that availability of the tests varies considerably between centers and countries. However, the myoclonic subtype guides the clinician toward a more precise differential diagnosis (see Table 1) and effective treatment strategy, and it helps to unravel the pathogenesis of myoclonus by creating homogenous groups.

Epilepsy is an additional feature in 82% of myoclonus syndromes, presenting either as CM in combination with epilepsy or myoclonic jerks as part of a myoclonic seizure. It is only described in genes with jerks originating from the cortex, as mutations in genes linked to noncortical myoclonus (hyperekplexia, all M-D syndromes, and Coffin-Lowry syndrome) rarely present with epileptic manifestations. The distinction between myoclonus and (myoclonic) epilepsy can be difficult to make, and seemingly minor differences in terminology can create confusion. Myoclonus epilepsy is a condition in which CM, often continuously present, and epilepsy occur independently, whereas myoclonic epilepsy is an attack of generalized convulsions starting with myoclonic jerks or predominantly characterized by myoclonic jerks. Jerks in both CM and myoclonic epilepsy are associated with EEG polyspikes or spike/ polyspike-wave complexes before the onset of an EMG burst. Confusion is not only the case in clinical practice but also in the literature, making it difficult to interpret many of the clinical presentations described. For instance, the phenotype associated with MYC/ATX-GOSR2 has been called an epileptic syndrome with myoclonic seizures (progressive myoclonus epilepsy type 6) in articles from the field of epilepsy, as opposed to a syndrome with prominent cortical myoclonus in combination with epilepsy (progressive myoclonus ataxia) in articles from the field of movement disorders. Particularly in the fields of movement disorders and epilepsy, the phenotype is a decisive factor for further diagnostics, and inaccuracy of descriptions can lead to erroneous genotype-phenotype relationships. Ongoing discussion and consensus meetings between experts in both fields are necessary to accomplish a consistent terminology with clear definitions that could easily be implemented in clinical practice.

Cognitive problems including cognitive decline and psychomotor retardation have been reported in all but 5 genetic disorders, MYC/DYT-SGCE, MYC/DYT-KCTD17, mUPD7 (based on loss of SGCE-gene), DYT-ANO3, and the hyperekplexias. Other nonmotor features, particularly psychiatric disorders and behavioral problems, are also being recognized as part of the phenotype of certain movement disorders (eg, dystonia). In disorders with cortical myoclonus, almost half the patients experience symptoms of depression or anxiety. Underestimation of these nonmotor features is likely, as we have only recently started considering this to be part of the phenotype. Future case descriptions of myoclonus syndromes should include details on cognition, psychiatric symptoms, and behavioral changes. The clinician should be aware of the high occurrence of nonmotor features in patients with myoclonus syndromes. These are features that impact the patient’s life and his or her family, and they require proper guidance and counseling.

Just as the presence of accompanying signs and symptoms can guide clinicians to a refined differential diagnosis, absence of an accompanying movement disorder proves a useful observation, as it points toward the related disorders, hyperekplexia and myoclonic epileptic encephalopathies. Hyperekplexia is characterized by 3 clinical symptoms: generalized stiffness at birth, excessive startle reflexes, and generalized stiffness following a startle. Genetic studies have shown mutations in different parts of the inhibitory glycine receptor complex, located in the postsynaptic membrane of glycergic and mixed GABAergic neurons. Synaptic inhibition in the brain stem and spinal cord is impaired as a result of a defect in 1 of these 3 genes. With regard to the genes identified in epileptic encephalopathies with prominent myoclonic jerks, a majority of these disorders share a phenotype that includes early disease onset (in the first 18 months of life) and a progressive course resulting in refractory epilepsy.
and severe cognitive decline. However, some genetic disorders are extremely rare (eg, CARS2), and those phenotypes are likely to be expanded in the coming years.

**Conclusion**

In collaboration with the MDS Task Force, we present a new nomenclature that includes 67 genetically determined myoclonus syndromes. As is apparent from this current list, numerous genes are linked to myoclonus syndromes, and prioritizing putative causative genes based on corresponding accompanying signs or symptoms and clinical clues could accelerate the identification of a molecular diagnosis in individual cases. Furthermore, it shows the additional value of electrophysiological testing in patients with myoclonus syndromes, as it may lead to a more refined differential diagnosis and therapeutic strategy. The current nomenclature can be used as a framework to add newly discovered genes in a systematic way and can be used for movement disorder (myoclonus) next-generation sequencing diagnostics. In the near future, genetically determined myoclonus syndromes can be uploaded in the searchable online database, the Movement Disorder Society Genetic Mutation Database, MDSGene (www.MDSGene.org), to provide an online, browsable database of hereditary myoclonus syndromes.110
